Corrosion in Petroleum Refining and Petrochemical Operations

Revised by Russell D. Kane, Honeywell Process Solutions, Honeywell International, Inc.

CORROSION has often been considered as an unavoidable part of petroleum refining and petrochemical operations. Partially due to this historical view of corrosion, one of the primary causes of operational problems in refining and petrochemical operations is corrosion. Corrosion problems increase operating and maintenance costs substantially. Time-dependent degradation due to corrosion usually defines scheduled and unscheduled shutdowns so that corrosion damage in piping and equipment can be inspected and/or repaired. This operational scenario can be extremely expensive. Single-incidence costs of major failures and related releases have been documented in the range of \$35 to \$50 million. Based on the current assessment of corrosion costs, the total annual direct cost of corrosion is estimated at \$3.7 billion. Of this total, maintenance-related expenses are estimated at \$1.8 billion, vessel turnaround expenses at \$1.4 billion, and fouling costs are approximately \$0.5 billion annually.

The potential for corrosion in refineries and petrochemical plants may be inherent to some processes, but costly and damaging equipment losses are not. Much work is being done to adapt process control technologies to integrate corrosion monitoring on an online, real-time basis to increase productivity (i.e., increase run time and decrease time associated with turnaround inspections). With this continual drive to increase productivity, the new vision of corrosion is that it is another process variable that can be continuously monitored, assessed, and controlled. In certain cases, process engineers have even been able to “see” new aspects of process chemistry through the information that their new view of corrosion data can bring. Certainly, corrosion engineers also benefit by having a greater appreciation of the actual process variations through having access to online data from which they can gauge their relative impact on corrosion.

To accomplish the aforementioned paradigm shift in corrosion technology, plant engineers are using new real-time, online measurement technologies (e.g., monitoring of electrochemical corrosion and pitting, advanced electric resistance corrosion measurements, hydrogen permeation monitoring, and online inspection)

along with improvements in handling and integration methods of electronic data that are now being introduced. Simultaneously, engineers are getting access to predictive software that rapidly queries complex engineer databases, makes flow modeling calculations, and applies expert rules for assessment of corrosivity and/or materials selection. This basically has resulted in a joining of online monitoring, inspection technologies, computer science, and process control information with real-time feed to process and corrosion engineers over global companywide information networks. The “replace when it fails” approach is receding into the past; facilities management today (2006) is embracing new technologies and starting to appreciate the actual value in terms of increased throughput, productivity, and profitability that this new approach offers. It has capabilities to increase unit run time between major inspections, reduce the time and expense associated with turnaround or inline inspections, and reduce major upsets that cause most of the unplanned shutdowns. The end result is the ability to know on a practical basis of how “hard” facilities can be pushed in the effort to increase productivity before excessive corrosion damage will result. This also allows the process engineers to understand the impact of their changes (i.e., feed and process control actions) to implement true process control and, eventually, asset management.

Often, anything that can be safely done to keep a process unit on stream for long periods of time will be of great benefit. A large proportion of corrosion problems are actually caused by start-up or shutdowns. For example, when equipment is opened to the atmosphere for inspection and repair, metal surfaces covered with (oftentimes, sulfur-containing) corrosion products will be exposed to air and moisture. This can lead to pitting and other forms of localized corrosion and stress-corrosion cracking unless preventive measures are implemented. When equipment is washed with water during a shutdown, corrosion can be caused by pockets of water left in the process units and associated piping.

Most petroleum refining and petrochemical plant operations involve flammable hydrocarbon streams, highly toxic or explosive gases, and

strong acids or caustics that are often at elevated temperatures and pressures. Among the many metals and alloys that are available, relatively few are used for the construction of process equipment and piping (Ref 1) due to the adverse influence on cost. However, materials used in process units include a wide variety of alloys, including carbon steel, cast irons, low-alloy steels, and stainless steels, and, to a much lesser degree, aluminum, copper, nickel, and expensive titanium- and nickel-base alloys. This article presents the primary considerations and mechanisms for corrosion and how they are involved in the selection of materials for process equipment in refineries and petrochemical plants. Over the past two decades, a substantial amount of new information has been obtained from laboratory simulation of process environments involving exposure to naphthenic acids and sulfur compounds at elevated temperature, and to lower-temperature wet hydrogen sulfide (H_2S) environments, including alkaline sour water. In addition, specific information on mechanical properties, corrosion, sulfide stress cracking (SSC), hydrogen-induced cracking (HIC), stress-oriented hydrogen-induced cracking (SOHIC), hydrogen embrittlement cracking (HEC), stress-corrosion cracking (SCC), velocity-accelerated corrosion, erosion-corrosion, and corrosion control is provided herein.

Materials Selection

The selection of materials of construction has a significant impact on the operability, economics, and reliability of refining units and petrochemical plants. For this reason, materials selection should be a cooperative effort between the materials engineer and plant operations and maintenance personnel. Reliability can often be equated to predictable materials performance under a wide range of exposure conditions (i.e., operating envelope). Ideally, a material should provide some type of warning before it fails; materials that fracture spontaneously and without bulging as a result of brittle fracture, SCC, or hydrogen embrittlement should be avoided. Uniform corrosion of equipment can be readily

detected by various inspection techniques. In contrast, isolated pitting is potentially much more serious, because leakage can occur at highly localized areas that are difficult to detect. Therefore, new monitoring techniques that can differentiate general from localized corrosion can be of substantial benefit to unit operators and managers interested in process control and plant asset management. The effect of environment on the mechanical properties of a material can also be significant. Certain exposure conditions (e.g., exposure to wet H₂S environments) can convert a normally ductile material such as carbon steel into a very brittle material that may fail without warning. A material must not only be suitable for normal process conditions but must also be able to handle transient conditions encountered during start-up, shutdown, emergencies, or extended standby. It is often during these time periods that equipment suffers serious deterioration or that failure occurs. With online monitoring techniques, these conditions can now be assessed on a real-time basis to provide additional input as to the consequences of these situations.

Of particular concern is what will happen to equipment during a fire or even high-temperature process excursions. Unexpected exposure to elevated temperatures can not only affect the metallurgical structure of the material and its related mechanical properties but can also produce detrimental side effects in terms of lost ductility and increased susceptibility to corrosion and/or SCC. Although all possible precautions should be taken to minimize the probability of a fire, the engineer responsible for materials selection must recognize that a fire or temperature excursions may occur and that the equipment is expected to retain its integrity in order to avoid fueling the fire. This often limits the application of materials with low melting points or those that may thermally decompose (i.e., nonmetallics and polymer-based composites) or become subject to damage by thermal shock when fire-fighting water is applied, particularly in the case of refinery piping and equipment used to handle highly flammable hydrocarbon streams. On the other hand, fire resistance need not be considered for cooling-water or instrument-air systems.

Although petrochemical plants may include some processes that involve nonflammable or nonhazardous streams, most equipment must be resistant to fires. For example, lack of fire resistance rules out the use of plastic components in refineries and petrochemical plants despite their excellent resistance to many types of corrosives. In addition, plastic components tend to be damaged by stream-out during a shutdown; this is required in order to free components of hydrocarbon residues and vapor before inspection or maintenance operations.

The final step in the materials selection process is a reliability review of the materials and the corrosion control techniques that were selected. There must be total assurance that a plant will provide reliable service under all conditions,

including those that occur during start-ups, shutdowns, downtime, standby, and other emergencies that may be presented.

Principal Materials

Materials selection criteria for a number of ferrous and nonferrous alloys used in petroleum refining and petrochemical applications are presented in this section. Additional information on selecting the proper metal or alloy is available in the article "Materials Selection for Corrosion Control" in *Corrosion: Fundamentals, Testing, and Protection*, Volume 13A of *ASM Handbook*, 2003.

Carbon and Low-Alloy Steels. Carbon steel is probably used for at least 80% of all components in refineries and petrochemical plants. The simple rationale for the extensive use of steel is that it is inexpensive, readily available, easily fabricated (e.g., bending, forming, and shop and field welding), and can be postweld heat treated when needed. Every effort is made to use carbon steel, even if process changes are required to obtain satisfactory service from carbon steel (Ref 2). For example, process temperatures can be decreased, hydrocarbon streams dried up, or additives such as inhibitors or neutralizers injected in order to reduce potential corrosion problems with carbon steel (Ref 3). In refineries, fractionation towers, separator drums, heat-exchanger shells, storage tanks, most piping, and all structures are generally fabricated from carbon steel. Carbon and low-alloy steels of carbon-molybdenum (C-Mo) or carbon-chromium-molybdenum (C-Cr-Mo) chemistry are the most widely used in plant construction. A C-0.5Mo steel can offer substantial savings over carbon steels at temperatures between 425 and 540 °C (800 and 1000 °F) because of increased temperature resistance (i.e., strength retention). The C-0.5Mo steel was originally considered significantly more resistant than carbon steel to high-temperature hydrogen attack (HTHA). It has been extensively used for reactor vessels, heat-exchanger shells, separator drums, and piping for processes involving hydrogen at temperatures above 260 °C (500 °F). However, service and inspection data have limited these expectations under conditions of long-term hydrogen exposure on C-0.5Mo steel. As a result, low-alloy steels are now preferred for new construction and repairs. Revised serviceability plots for HTHA (i.e., Nelson curves) of common constructional steels used in refinery equipment have been prepared and are continually being updated by the American Petroleum Institute (API), which takes into account new service experience, failures, and so on. See the section "Hydrogen Attack" in this article.

Low-alloy steels are widely used for refinery service and are generally the C-Cr-Mo steels containing between 1 and 9% Cr. These steels have excellent strength retention, resistance to high-temperature sulfidic corrosion (due to their increased chromium levels), and resistance to

HTHA. To improve resistance to hydrogen stress cracking (including SSC in wet H₂S environments), these low-alloy steels normally require postweld heat treatment. The benefits of postweld heat treatment are generally considered to be the associated reduction in residual tensile stresses in the area of the weldment, and the reduction in hardness and changes in the carbide morphology of weld heat-affected zones (HAZ). For refinery reactor vessels, which operate at high temperatures and pressures, 2.25Cr-1Mo steel is widely used. For improved corrosion resistance, these are often overlaid with stainless steels such as type 347. Other applications for low-alloy steels are furnace tubes, heat-exchangers shells, piping, and separator drums. Additional information is provided in the articles "Corrosion of Wrought Carbon Steels" and "Corrosion of Wrought Low-Alloy Steels" in *Corrosion: Materials*, Volume 13B of *ASM Handbook*, 2005.

Stainless steels are extensively used in petrochemical plants because of the highly corrosive nature of the catalysts, process constituents, and solvents that are often used. In refineries, stainless steels have been primarily limited to applications involving high-temperature sulfidic and naphthenic acid corrosion and other forms of high-temperature attack (Ref 4). However, they are also found in increasing regularity in sour alkaline water applications (Ref 5). An important consideration when using stainless steels is that many of the conventional austenitic stainless steels (300-series) will pit or suffer SCC in the presence of chlorides and water to a varying degree, depending on other species such as oxygen and sulfides (Ref 6). However, there are many new higher-alloy stainless steels that have higher resistance to pitting and localized attack. Some of these are shown in Table 1. They have increased amounts of chromium, molybdenum, tungsten, and nitrogen that enhance passivity against more hostile process environments.

The minimum stainless alloys in terms of corrosion resistance are generally considered to be the martensitic stainless steels, such as type 410 (S41000). This material must be postweld heat treated to avoid hydrogen cracking problems as a result of exposure to processes that contain H₂S or other hydrogenating environments. Typical applications include pump components, fasteners, valve trim, turbine blades, tray valves, and other tray components in fractionation towers. Low-carbon varieties of type 410 stainless steel (S41008) are preferred for furnace tubes and piping, often in combination with aluminizing for increased corrosion resistance under conditions that will cause sulfidation. Ferritic stainless steels, such as type 405 (S40500), are less subject to hydrogen stress cracking and are therefore a better choice than type 410 (S41000) stainless steel for vessel linings that are attached by welding (Ref 7).

Austenitic stainless steels, such as type 304 (S30400) or type 316 (S31600), have excellent corrosion resistance but, as mentioned

previously, are generally considered to be susceptible to SCC by chlorides at temperatures above 60 °C (140 °F). If sensitized, they are also subject to SCC in aqueous chloride environments at lower temperatures, and susceptibility may also include SCC in polythionic acids (Ref 8, 9) formed by the combination of moisture, sulfur components, and oxygen when process equipment is opened to air. Typical applications include linings and tray components in fractionation towers; piping; heat-exchanger tubes; reactor cladding; tubes and tube hangers in furnaces; various components for compressors, turbines, pumps, and valves; and reboiler tubes.

In many aqueous refinery environments, susceptibility of stainless steels (and nickel-base alloys) to corrosion and localized attack (e.g., pitting, crevice corrosion, and SCC) has been found to be related to the pitting resistance equivalent number (PREN), which is given by the following formula (Ref 10):

$$\text{PREN} = \text{Cr} + 3.3\text{Mo} + 1.5(\text{W} + \text{Nb}) + x\text{N} \quad (\text{Eq 1})$$

where $x = 0$ for martensitic and ferritic stainless steels, $x = 16$ for duplex stainless steels, and $x = 30$ for austenitic alloys. This relationship is heavily based on performance of these alloys in elevated-temperature aqueous, chloride-containing environments in aerated or oxidizing conditions. In reducing environments with sulfides and chlorides, the value for x can be limited to 11 (versus 16 and 30 as given previously) due to the lesser role of nitrogen in maintaining passivity under these conditions (Ref 11). Based on the aforementioned PREN

relationship, recent refinery applications have included greater use of duplex stainless steels, such as alloy 2205 (S31803) and alloy 2507 (S32750), or high-alloyed austenitic stainless steels, such as alloy 904L (N08904) and alloy AL6XN (N08367). These alloys have PREN values in the range of 30 to over 40 versus the more commonly used type 316 stainless steel with a PREN value of 24. Applications have included uses in cooling water service, process heat exchangers, and sour water systems, where added corrosion and SCC resistance over that of 300-series austenitic stainless steels was needed, and with a cost-savings over conventionally used nickel alloys.

For nonaqueous conditions involving exposure to high-temperature sulfidic or naphthenic crude oil environments, resistance to corrosion has been mainly related to simply the sum of the chromium and molybdenum concentration (Ref 12). For further information, see the article "Corrosion of Wrought Stainless Steels" in *Corrosion: Materials*, Volume 13B of *ASM Handbook*, 2005.

Cast irons, because of the inherent brittleness and low strength found in many grades, are normally not used for pressure-retaining components for handling flammable hydrocarbons. The main exceptions are pump and valve components, ejectors, jets, strainers, and fittings in which the high hardness of cast iron can have a beneficial effect in reducing the velocity effects of corrosion, such as impingement, erosion, and cavitation. High-silicon cast irons (with 14% Si) are extremely corrosion resistant because of a passive surface layer of silicon oxide that forms during exposure to many chemical environments (except hydrofluoric acid). Typical refinery and

petrochemical plant applications include valve and pump components for corrosive service. High-nickel cast irons (with 13 to 36% Ni and up to 6% Cr) have excellent corrosion, wear, and high-temperature resistance because of the relatively high alloy content (Ref 13). Typical uses are valve components, pump components, dampers, diffusers, tray components, and compressor parts. Additional information is provided in the article "Corrosion of Cast Irons" in *Corrosion: Materials*, Volume 13B of *ASM Handbook*, 2005.

Copper and Aluminum Alloys. These materials are used extensively in water service and commonly are restricted to applications below 260 °C (500 °F) because of strength limitations. Admiralty brass (C44300) tubes have been extensively used in water-cooled condensers and coolers at most refineries. However, in general, copper alloys suffer accelerated corrosion in both acidic and alkaline environments containing sulfur species. Therefore, they have often performed poorly in overhead condensers, compressor aftercoolers, and other sour water applications and other locations where high concentrations of H₂S and ammonia are encountered in aqueous condensate. This condition can also be exacerbated by the influence of flow-induced turbulence. Even when alloyed with substantial nickel (e.g., cupronickel and alloy 400), the performance of these alloys is inferior to comparably priced stainless or nickel-base alloys. The usual mode of corrosion failure of brass and copper alloys in refinery applications includes excessive corrosion rate, pitting, dezincification, and ammonia SCC.

Aluminum alloys, at one time, were proposed for refinery use as a substitute for carbon steel and admiralty brass (C44300) heat-exchanger tubes in cooling-water service (Ref 14–16). Aluminum tubes were found to be highly resistant to aqueous sulfide corrosion in overhead condensers. Unfortunately, fouling and pitting corrosion on the water side have always been a problem, and except for certain limited applications, most refineries do not use aluminum tubes. The only other major refinery use of aluminum has been in vacuum towers, in which aluminum or aluminum coatings can provide resistance (at relatively low-flow conditions) to the naphthenic acid corrosion of tray components. Aluminized coatings are also used to protect low-alloy steels against high-temperature sulfidic corrosion in the absence of moisture and/or chlorides. Additional information is available in the articles "Corrosion of Copper and Copper Alloys" and "Corrosion of Aluminum and Aluminum Alloys" in *Corrosion: Materials*, Volume 13B of *ASM Handbook*, 2005.

Nickel and nickel alloys are especially used for corrosion resistance in sulfuric acid, hydrochloric acid, hydrofluoric acid, and caustic environments, all of which can result in corrosion problems in many materials of construction in certain refinery and petrochemical operations (Ref 17). As an alloying element in austenitic

(a) Maximum allowable concentration unless range is given

alloys, nickel is important in reducing susceptibility to chloride SCC in elevated-temperature solutions. Generally, SCC resistance increases with nickel content above approximately 8% (Fig. 1) (Ref 18). In the range of approximately 40% Ni, many stainless alloys are resistant to chloride SCC in aerated chloride-containing solutions. However, where chlorides are present in combination with sulfides in aqueous acidic environments at elevated temperature, SCC can still be observed. Higher resistance to SCC is obtained through additional alloying with nickel, chromium, molybdenum, and nitrogen. Similar to stainless steels, resistance to SCC in nickel-base alloys is also generally found to be related to pitting susceptibility through the commonly used formula for PREN discussed previously in this article for stainless steels.

Nickel also forms the basis for many high-temperature alloys. However, nickel alloys not containing chromium or molybdenum can be attacked and embrittled by sulfur-bearing gases (sulfidic attack) and sour water solutions (ammonium bisulfide corrosion) at elevated temperatures. Alloy 400 (N04400), a nickel-copper alloy, is extensively used as a lining for carbon steel equipment to prevent corrosion by hydrochloric acid and chloride salts (Ref 19). For the same reason, alloy 400 (N04400) tubes have been used in overhead condensers. Alloy 400 (N04400) is also used against corrosion by hydrofluoric acid. However, in the presence of sour water environments, this nickel-copper-containing alloy can show accelerated corrosion under conditions of elevated temperature and high flow-induced turbulence. Alternative stainless or nickel-base alloys may be preferred for some applications.

High-nickel alloys with high levels of chromium and molybdenum, such as alloy 825

(N08825) and alloy 625 (N06625), are used to reduce the polythionic acid corrosion of flare-stack tips, as can be experienced with conventional stainless steels. The nickel-molybdenum alloys, such as alloy B-2 (N10665) and B-3 (N10675), are particularly well suited for handling hydrochloric acid at all concentrations and temperatures (including the boiling point) but are attacked if exposed to oxidizing salts or aerated environments (Ref 20, 21). Alloy B (N10001), alloy C-4 (N06455), and alloy C-276 (N10276) have excellent resistance to all concentrations of sulfuric acid up to at least 95 °C (200 °F).

Newer alloys have been developed specifically for resistance to environments containing sulfides and chlorides, such as alloy 686 (N06686), for carburization resistance, such as alloy 214 (N07214), and nickel/cobalt-base alloys with combined resistance to multiple corrodants in complex process streams, such as alloy 556 (R30556). Although usually expensive, these alloys are used for specific applications to overcome unusually severe corrosion problems. Additional information is provided in the article "Corrosion of Nickel and Nickel-Base Alloys" in *Corrosion: Materials*, Volume 13B of *ASM Handbook*, 2005.

Titanium and Titanium Alloys. These alloys have been extensively used in certain petrochemical processes where high corrosion resistance is needed. Titanium, however, is not generally considered a high-temperature metal; welding and cutting must be done under inert gas atmospheres with specific procedures to prevent embrittlement (Ref 22, 23). From a practical point of view, the use of titanium in refinery and petrochemical plant service is limited to temperatures below 260 °C (500 °F) (Ref 24, 25). If hydrogen is present, temperatures should not exceed 175 °C (350 °F) in order to prevent embrittlement due to hydride formation. Hydrogen embrittlement of titanium can also occur as a result of a galvanic couple to a less noble material such as steel in elevated-temperature aqueous solution. Titanium is fully resistant to many process streams due to its reactive nature, which allows it to readily form a passive TiO₂ surface layer that is both tough and chemically resistant. Tubes made from Ti-grade 2 (R50400) are extensively used in

overhead coolers and condensers on a number of refinery units to prevent corrosion by aqueous chlorides, sulfides, and sulfur dioxide. These tubes can corrode, however, beneath acidic deposits. Titanium tubes are often required when seawater or brackish water is used for cooling. Where underdeposit corrosion of pure titanium is a problem, Ti-grade 12 (R53400), alloyed with nickel and molybdenum, should be considered. Anodizing and high-temperature air oxidizing of Ti-grade 2 (R50400) have been shown to be beneficial from a corrosion point of view (Ref 26).

More recently, new titanium alloys, which contain low-level alloying additions of noble metals such as palladium in Ti-grade 7 (R52400) or ruthenium in Ti-grade 26 (R52404), have been effectively used to reduce crevice and pitting attack and underdeposit corrosion. A list of titanium alloys and their compositions is given in Table 2. Additional information is provided in the article "Corrosion of Titanium and Titanium Alloys" in *Corrosion: Materials*, Volume 13B of *ASM Handbook*, 2005.

Codes and Standard Specifications

Rules for the design, fabrication, and inspection of pressure vessels, piping, and tanks are provided by codes that have been developed by industry and/or regulatory agencies in various countries, as shown by the listing in Table 3 (see also the "Appendix: Industry Standards" at the conclusion of this article). In the United States, the American National Standards Institute/American Society of Mechanical Engineers (ANSI/ASME) Boiler and Pressure Vessel Code, section VIII, which covers unfired pressure vessels, is used by most industries and fabricators. It is usually mandatory that the code be followed in process applications. Therefore, the first step in selecting materials of construction is to know what the code covers and what it does not.

The ANSI/ASME Boiler and Pressure Vessel Code also provides a list of acceptable materials for pressure-containing applications and allowable stress values for each material. The detailed specifications for these steels are provided in Sections II A and II B of the code, which are

based on ASTM International and UNS standard specifications (Table 4). The code also provides the method for calculating the required minimum thickness of various components based on design temperature and pressure. The need for heat treating during fabrication and the inspection requirements are also defined based on the alloy selected and the pressure-wall thickness. For welded pressure vessels, Section IX of the code defines the requirements for qualifying the welding process to be used.

The code does not consider the effect of process environment on the materials selected. It recognizes that corrosion can and does occur, and it provides rules for including corrosion allowances in the calculation of the required pressure-wall thickness; however, suitable values for the corrosion allowance must be specified by the designer. It is also the responsibility of the designer to specify any special heat treatments, hardness limitations, or other

details that may be required as a result of environmental factors. Similarly, the designer must determine accurately the full range of likely operating conditions, including upsets that may be encountered so that the design criteria are met.

Mechanical Properties

Elevated-Temperature Properties. As mentioned in the preceding section, the applicable code will specify the allowable stress that is to be used for a particular material of construction in the design of a given piece of equipment. This allowable stress is based on the temperature to which the equipment will be exposed for long periods of time. Steels operating under normal plant conditions can be exposed to these temperatures for extensive periods of time without adverse effects on their allowable strength if

there is no corrosion. As working temperatures increase, the mechanical strength of most materials decreases. In actual practice, however, a material is more likely to fail at elevated temperatures by creep or stress rupture than from simply a decrease in short-term tensile or yield strength properties.

For example, Table 5 shows the short-term, elevated-temperature yield strengths of several carbon and low-alloy steels. As can be seen from the tabulated data, all three steels (carbon steel, C-0.5Mo steel, and 2.25Cr-1Mo steel) have acceptable yield strength values up to 480 °C (900 °F). These values do not, however, adequately represent the long-term resistance of the steels to creep when stressed at elevated temperatures. Instead, creep resistance values are a more accurate measure of elevated-temperature mechanical strength. Creep resistance values are obtained from creep tests (elongation versus time) and stress-rupture tests (stress versus time-to-failure) at elevated temperatures over a period of 10,000 h and are usually extrapolated to 100,000 h. Table 6 shows creep resistance values of the three steels discussed previously. The deterioration of creep resistance of carbon steel at 480 and 540 °C (900 and 1000 °F) is readily apparent, as is the marked improvement afforded by use of 2.25Cr-1Mo steel. Table 7 lists suggested maximum service temperatures for five different steels and alloys based on creep-rupture data. In some applications, such as furnace tubes, code-allowable stresses need not be followed, and equipment may be operated at temperatures and stresses that can lead to creep failure, provided accurate prediction of service life has been made. In order to predict failure with greater accuracy, equipment operating in the creep range should be periodically inspected as the design life is approached. Guidelines for design, service life prediction, and risk-based inspection of refinery equipment in refinery service are given in industry standards such as API 580 and API 579 (Ref 27, 28).

Hardness. The hardness of steels is not considered by the code as a specified property. Whether it is the result of forming, heat

treatment, or welding operations, hardness (or, more properly, the resultant metallurgical structure of the steel) can have a distinct effect on the suitability of steel for a particular application or service environment. Although carbon steel normally has low hardness values, cooling from elevated temperatures, such as those encountered during mill processes such as quenching or normalizing or during fabrication or repair welding, may result in changes in hardness, hardness gradients, or localized hard zones.

Existing refinery experience indicates that if hardness values exceed 200 HB, carbon steel may be subject to cracking in aqueous alkaline sour water environments. This case is typical for susceptibility to SCC in pressure vessel weldments. For this reason, it is often necessary to set a maximum hardness limit for carbon steel and welds used in pressure vessels. In some cases, it is desirable to impose a uniform hardness limitation on all pieces of fabricated equipment, because the originally intended service application may be changed at some future date to one in which the component would be exposed to an aqueous sulfide environment. A high hardness value is also indicative of an increase in tensile strength and a corresponding decrease in ductility. Commonly produced plate steels

(not having special thermomechanical processing used to enhance properties) with excessively high hardness values may also be expected to behave in a brittle manner under extreme conditions of low temperature, presence of pre-existing cracking, and/or rapid loading. Low-alloy steels often require postweld heat treatment after welding to reduce hardness in the weld area and to reduce the stresses associated with welding.

In some cases, hardness is not a good indicator of crack susceptibility. This is the case when it comes to resistance to HIC of steels in wet H₂S environments. This type of cracking occurs as a result of hydrogen absorption into the steel from sulfide corrosion that collects at internal interfaces in the material, mostly around inclusions. Susceptibility to HIC actually is greater in low-strength (low-hardness) steels and is related to the sulfur content and rolling practice used in making the steel, and its resultant sulfide inclusion morphology.

Fatigue Strength. Certain components, such as compressors or pumps, require materials with good fatigue-resistance properties. Fatigue resistance also needs to be considered when bolting and piping materials are selected. Fatigue resistance is the ability of a load-carrying component

to resist fracture from cycles of repeatedly applied forces, such as vibrational or rotational stresses. One common rule of thumb is to limit the average fatigue stress to approximately one-half the ultimate tensile strength of the material involved. Because fatigue involves crack formation, crack propagation, and residual load-carrying capabilities, several mechanical properties are involved in determining fatigue resistance. Obviously, higher strength will help a material resist crack initiation. However, in many cases, materials and equipment have cracklike indications or defects that can act as pre-existing cracks. In these cases, other factors need to be considered in assessing resistance to fatigue crack propagation and ultimate failure. These factors include the fracture toughness of the steel, which is often related to the cleanliness of the material, and how it responds under plastic strain. Material with a low inclusion content and fine grains is commonly found to have high fatigue resistance, because the inclusions can be a source for internal crack initiation (or propagation), while fine grains will assist in allowing the crystallographic planes to slip without concentrating the associated strain.

Low-Temperature Properties. Carbon steel begins to lose its toughness and ductility as service temperatures decrease below ambient. Because most equipment in refineries and petrochemical plants is made of carbon steel, insufficient low-temperature toughness could represent a potentially serious problem. Fortunately, few operations are carried out at low temperatures, and most equipment made of carbon steel operates at temperatures ranging from ambient to approximately 425 °C (800 °F). However, equipment is normally exposed to ambient temperature during shutdown, which can pose a problem if the steel has inadequate low-temperature toughness. Certain refinery and petrochemical plant equipment and processes involved in cryogenic processes require special low-temperature toughness grades of steels, including liquefied-propane storage, ammonia storage, solvent dewaxing units, and liquefied petroleum gas processing. It is possible, by specifying certain additional composition and metallurgical processing requirements, to obtain carbon and low-alloy steels that are suitable for temperatures as low as -45 °C (-50 °F), depending on thickness. To resist brittle fracture at lowered temperatures, steels should be fully killed, fine grained, normalized, and should have received postweld heat treatment. Additionally, low-temperature toughness is also improved through alloying additions of nickel and vanadium and/or through use of thermomechanically controlled processed steels.

Typical ASTM International standard specifications for carbon steels with enhanced ability to perform at low temperatures are given in Table 8. Steels alloyed with 2 to 9% Ni and austenitic stainless steels can extend the range of available notch-tough steels to even lower temperatures. The simplest quality-control test (although not always adequate) for ensuring

Table 5 Short-term, elevated-temperature yield strengths for refinery steels

proper notch toughness is the Charpy V-notch impact test carried out at the minimum design temperature, or lower. A minimum value of approximately 20.5 J (15 ft·lbf) is the usual acceptance criterion. The Charpy test is designed to simulate failure of a pressure vessel, containing a fabrication- or service-induced cracklike defect, by rapid crack propagation (brittle failure) when stressed at low temperatures.

Embrittlement Phenomena. There are a number of environmental effects on the mechanical properties of low-alloy steels and stainless steels used for refinery and petrochemical plant construction that need to be considered. In almost all cases, the effect is one of embrittlement due to an increase in hardness or a reduction in the notch ductility of the material. Detailed information on embrittlement mechanisms and the resulting fracture appearance can be found in the article “Visual Examination and Light Microscopy” in *Fractography*, Volume 12 of *ASM Handbook*, 1987. Embrittlement phenomena are also reviewed in the article “Embrittlement of Steels” in *Properties and Selection: Irons, Steels, and High-Performance Alloys*, Volume 1 of *ASM Handbook*, 1990.

Temper Embrittlement. This phenomenon causes a significant increase in the ductile-to-brittle transition temperature of low-alloy steels containing 1 to 3% Cr that are exposed to above 370 to 540 °C (700 to 1000 °F) for a prolonged period of time. Brittle failure at weld defects can occur when process equipment made from these steels is fully pressurized during start-up or shutdown. Therefore, pressure should be limited to 25% of design when temperatures are below 150 °C (300 °F) (Ref 29). Ideally, equipment made from steels that have become temper embrittled should be preheated to above 120 °C (250 °F) before pressurization following a shutdown. Temper embrittlement is caused by the segregation of residual steel elements to the grain boundaries, and this greatly reduces the intercrystalline (i.e., grain-boundary) strength. Limiting the acceptance levels of such elements as manganese, silicon, phosphorus, tin, antimony, and arsenic can improve the temper embrittlement resistance of 2.25Cr-0.5Mo, 2.25Cr-1Mo, and higher-alloyed chromium-molybdenum steels. Frequent nondestructive testing of major weld seams is recommended to determine if equipment has become embrittled.

885 °F (475 °C) **Embrittlement.** This phenomenon occurs in ferritic or martensitic stainless steels containing 12% or more chromium. It is manifested in material or equipment after long-term exposure to temperatures between 400 and 540 °C (750 and 1000 °F), hence the name 885 embrittlement. Heat treatment at approximately 620 °C (1150 °F), followed by rapid cooling, will usually restore ductility to embrittled stainless steels.

Sigma-Phase Embrittlement. The incidence of this phenomenon can occur in austenitic stainless as well as in straight-chromium (ferritic or martensitic) stainless steels as a result of prolonged high-temperature exposure. Sigma phase is nearly devoid of mechanical toughness and has a large influence on overall mechanical properties even at very low volume fractions relative to the bulk material. Of the austenitic stainless steels, the most susceptible compositions contain approximately 25% Cr and 20% Ni. The straight-chromium steels that are most susceptible to σ -phase formation contain 17% or more chromium. Sigma-phase formation increases room-temperature tensile strength and hardness while decreasing ductility to the point of extreme brittleness. As a result, cracks are very likely to develop during cooling from operating temperatures. Sigma phase most commonly forms in equipment operating in a temperature range of 650 to 750 °C (1200 to 1400 °F). Because σ -phase can be dissolved at temperatures above 980 °C (1800 °F), the original properties of stainless steels can be restored by a suitable heat treatment.

Creep embrittlement is the stress-dependent embrittlement of low-alloy steels operating in the creep range. The result is a reduction in the stress-rupture ductility. Creep embrittlement is commonly caused by the formation of precipitates within the grains, which results in the grain boundaries being softer than the material within the grains. Therefore, strain is concentrated in the grain boundaries, leading to premature failure. Detrimental effects can be eliminated by annealing the steel.

Fabricability

With very few exceptions, process equipment and piping are fabricated by welding wrought steels. The shells of pressure vessels are usually

made from rolled plate, while nozzles are forgings. This requires that the steels have sufficient ductility for forming and are readily weldable. Weldability of steels is important not only for initial fabrication but also for future field repairs or modifications. Weld repairs and postweld heat treatments can affect the mechanical properties of wrought components that have been processed by normalizing or quenching and tempering. This can leave the wrought material with a lower strength than expected, based solely on its mill processing and composition.

Welding may result in certain other problems. Hydrogen coming from moisture in certain weld consumables or during nonoptimal field welding conditions can become dissolved in liquid weld metal. This dissolved hydrogen can cause cracking during solidification, as well as embrittlement of the weld. Dissolved hydrogen in the material as a result of exposure to refinery wet H₂S service environments can also affect weldability and the subsequent performance of repair welds.

The risk of hydrogen cracking of weldments is reduced by the use of low-hydrogen electrodes, careful drying of electrodes, and close control of pre- and postweld heat treatments. Equipment exposed to wet H₂S service environments often needs to be baked prior to weld repairs to reduce or remove the accumulated hydrogen, which can lower weldability. In some severe cases, this can result in cracks being formed as a result of HTHA (Ref 30). Information on the effect of bake-out treatments and other wet H₂S repair techniques is presented later in this article in the section “Wet H₂S Cracking.”

Stress-relief or reheat cracking is intergranular cracking in the weld HAZ. The HAZ cracking occurs when weldments are heated during postweld heat treatment, or it occurs by subsequent exposure to elevated service temperatures. Low-alloy steels are especially susceptible to the aforementioned phenomena, but hydrogen cracking can occur with any of the ferritic steels if proper care is not taken.

Corrosion Resistance

The effects of the environment need to be considered when materials of construction are specified. General corrosion (uniform metal loss) is the easiest form of metal deterioration that can be considered in the design phase, because additional metal can be provided in the form of a corrosion allowance. It is also the easiest form of corrosion that can be detected by non-destructive testing techniques, because it is manifested to generally the same extent in all locations. Corrosion allowances in most cases range between 1 and 3 mm (0.04 and 0.12 in.), depending on the severity of the anticipated service conditions. In some particularly severe cases, local corrosion allowances can be increased to 5 mm (0.2 in.) or more where known impingement or turbulence is involved.

Table 8 ASTM International standard specifications for carbon steel with enhanced resistance to brittle fracture at lowered temperatures

Product form	Temperature/steel	
	To -30 °C (-20 °F)	To -45 °C (-50 °F)
Plate	A516, normalized (may require impact testing)	A516 normalized, stress relieved and Charpy impact tested
Pipe	A524	A333 grade 1 and grade 6
Tube	A210	A334 grade 1 and grade 6
Forgings	A727 and A350 grade LF1	A350 grade LF2
Fittings	A420 WPL6	A420 WPL6
Castings	A352 grade LCA	A352 grade LCB and grade LCC

In the case of pitting corrosion, it is possible to provide a pitting allowance. Because metal loss due to general corrosion is often not significant under pitting conditions, this approach would represent a rather expensive method of protecting equipment. Instead, it is generally more practical and advantageous to avoid process conditions that produce pitting or to change to a material that will not pit.

Until relatively recently, it was not possible to specifically identify pitting corrosion through corrosion monitoring except by after-the-fact coupon examination or inspection. However, newer corrosion-monitoring methods involving use of the electrochemical noise techniques and real-time data acquisition via control systems have made it possible to differentiate pitting activity from general corrosion and to identify these operating conditions before substantial damage has occurred. Figure 2 shows corrosion monitoring with pitting data obtained with multiple monitoring techniques (linear polarization resistance, electrochemical noise, and harmonic distortion analysis). It shows conditions involving cooling-water service where the general corrosion rate was lowered through chemical treatment and was under control, but where the susceptibility to pitting remained at critical levels. These results were later verified through visual examination of the probe elements, which were segments of cooling heat-exchanger tubing (Ref 31).

Stress-corrosion cracking is one of the most serious forms of metal deterioration, because it can result in extensive cracking and the catastrophic failure of equipment or considerable losses to an operating facility. Stress-corrosion cracks are very difficult to detect through online or offline inspection, because they can occur locally (often at areas of high residual or

applied tensile stress) and are not uniformly distributed over the metal surfaces. Austenitic stainless steels are highly susceptible to SCC in aqueous, chloride-containing environments and consequently are often avoided for the primary pressure boundary of components. They are often used as protective, internal linings that may fail but where the integrity of the equipment is not completely compromised.

Corrosion

For practical purposes, corrosion in refineries and petrochemical plants can be classified into two types of corrosion (Ref 32, 33):

- Low-temperature (aqueous) corrosion occurring below approximately 260 °C (500 °F) in the presence of water
- High-temperature (nonaqueous) corrosion occurring above approximately 205 °C (400 °F) in the presence of liquid or gaseous hydrocarbons

Carbon steel can be used to handle most hydrocarbon streams, except where corrosion is induced by the presence of contaminants present in the refined hydrocarbons or induced by upset conditions. In most cases, aqueous corrosion results from the presence of hydrogen chloride, H₂S and ammonia, as impurities in the feedstock, oxygen from air ingress into process equipment and tanks, lack of control of pH, oxygen or other species in cooling water, or from various related chemicals such as amine solvents or strong caustics and acids. These conditions often necessitate selective application of more resistant alloys. For high-temperature corrosion to take place, the presence of water is not

necessary. Corrosion can occur by the direct reaction between metal and impurities such as H₂S, sulfur species, and naphthenic acid in the environment (Ref 32–35).

Low-Temperature Corrosion

Most corrosion problems in refineries are not caused by hydrocarbons but, as briefly mentioned previously, by various associated chemical compounds, namely, water, H₂S, hydrochloric acid, hydrofluoric acid, sulfuric acid, caustics, and amine solvents (Ref 36). There are two principal sources of these compounds: feed-stock contaminants and process chemicals, including solvents, neutralizers, and catalysts. Generally, the same applies to corrosion problems in petrochemical plants, except that corrosion is also caused by organic acids, such as acetic acid, that may be used as solvents. In addition, corrosion problems are caused by the atmosphere (oxidation), cooling water, boiler feed water, steam condensate, and soil.

Low-Temperature Corrosion by Feed-Stock Contaminants

The major cause of low-temperature (and, for that matter, high-temperature) refinery corrosion is the presence of contaminants in crude oil as it is produced. Although some contaminants are removed during preliminary treating upstream of the refinery, some contaminants end up in refinery tankage, along with contaminants picked up in pipelines or marine tankers. Corrosives can also be formed during initial refinery operations. For example, potentially corrosive hydrogen chloride evolves in crude preheat furnaces from relatively harmless calcium and magnesium chlorides entrained in crude oil (Ref 37). In petrochemical plants, certain corrosives may have been introduced from upstream refinery and other process operations. Other corrosives, such as sulfur compounds, can form by conversion of corrosion products after exposure to air during shutdowns (i.e., polythionic acid). The following discussion focuses on the most important crude oil contaminants that have caused corrosion problems.

Air. During shutdowns or turnarounds, most plant equipment is exposed to air. Air also can enter the suction side of pumps if seals or connections are not tight, or in cases where tanks are vented to the atmosphere or develop negative pressure. In general, the air contamination of hydrocarbon streams has been more detrimental with regard to fouling than corrosion. However, air contamination has been cited as a cause of accelerated corrosion in vacuum transfer lines and vacuum towers of crude distillation units. Air contamination has supposedly increased the overhead corrosion of crude distillation towers, but this has been difficult to reconcile with the fact that oxygen in air reacts with H₂S to form polysulfides, which tend to inhibit corrosion. In aqueous systems, air contamination also leads to

Fig. 2 Real-time monitoring of chemical injection in a cooling-water system with online corrosion rate and pitting tendencies (localization index). October 10—Chemical treatment program transition: Inhibitor was turned off, acid addition was stopped, blowdown was increased, and dispersant was added. October 12—A low-pH event caused an increase in corrosion rate and a change in corrosion mechanism. Within 24 h, pit initiation and propagation were indicated. October 15—Inhibitor injection resumed: Although inhibitor injection was restarted, complete passivation was not achieved. A short-term reduction in localized corrosion activity was observed, but this increased again. Two weeks following the low-pH event, significant localized corrosion activity was still indicated. The pitting was later confirmed by analysis of the tubular flow-through probe elements.

excessive pitting, particularly when the environment also contains either H_2S or chloride salts.

Water. Water is found in all crude oils to a certain degree and is difficult to remove completely. In addition, water originates with stripping steam for fractionation towers and is produced in hydrotreating operations. Water not only functions as an electrolyte but also hydrolyzes certain inorganic chlorides to hydrogen chloride, which, in turn, functions as a corrodant as well. Water is primarily responsible for various forms of corrosion in fractionation tower overhead systems. In general, whenever equipment can be kept dry through suitable process or equipment changes, corrosion problems will be minimized. Furthermore, additional "wash" water can be added to a process stream, further diluting various potentially corrosive species to acceptable levels.

The combination of water and air can be especially detrimental. Moisture and air are drawn into storage tanks during normal "breathing" as a result of pumping and changes in temperature. Tank activity and corrosion are closely interrelated. Because crude and heavy oils form a protective oil film on the working areas of a tank shell, corrosion is generally limited to the top shell ring and the underside of the roof. Tank bottom corrosion occurs mostly with crude oil tanks and is caused by water and salt entrained in the crude oil. A layer of water usually settles out and can become highly corrosive. Alternate exposure to sour crude oils and saltwater causes especially severe corrosion (Ref 38). Mill scale tends to accelerate tank bottom corrosion, because cracks in the mill scale form anodic areas that pit, while the surrounding area acts as the cathode.

Light hydrocarbon stocks do not form protective oil films, and corrosion occurs primarily at the middle shell rings, because these are exposed to more wetting and drying cycles than other tank areas (Ref 39). Corrosion is in the form of pitting under globules of water that attach themselves to the tank wall. Pitting can become so extensive that metal loss generally appears as more or less uniform corrosion. The rate of corrosion is proportional to the water and air content of light stocks. Contamination from chloride and H_2S also accelerates attack.

Hydrogen Sulfide. Sour crude oils and gases that contain H_2S are handled by most refineries (Ref 40). Hydrogen sulfide is also present in some feed stocks handled by petrochemical plants. During processing at elevated temperatures, H_2S and many other sulfur species are also formed by the decomposition of organic sulfur compounds that are present. Corrosion of steel by H_2S forms the familiar black iron sulfide film seen in almost all refinery equipment (Ref 41). Hydrogen sulfide with ammonia are the main constituents of refinery sour waters that can cause severe corrosion problems in overhead systems of certain fractionation towers, in hydrocracker and hydrotreater effluent streams, in the vapor recovery (light ends) section of fluid catalytic cracking units, in sour water stripping

units, and in sulfur recovery units (Ref 42, 43). These are discussed in greater detail in the section "Sour Water" in this article.

In general, carbon steel has fairly good resistance to aqueous sulfide corrosion, because a protective iron sulfide film is formed (Ref 44). However, conditions of air ingress, chlorides, cyanides and/or high flow-induced turbulence can remove normally protective films to increase the susceptibility to general and/or pitting corrosion, local wall loss, and hydrogen charging of the steel.

To avoid SSC in a wet H_2S system, hard welds (above 200 HB) need to be avoided. If necessary, suitable postweld heat treatment may need to be performed (Ref 45). Excessive localized corrosion in vessels has been resolved by selective lining with alloy 400 (N04400), but this alloy can be less resistant than carbon steel or other corrosion-resistant alloys to aqueous sulfide corrosion at temperatures above 100 °C (212 °F). If significant amounts of chlorides are not present, lining vessels with type 405 (S40500) or type 304 (S30400) stainless steels can be considered. Ti-grade 2 (R50400) tubes have been used as replacements for carbon steel tubes to control aqueous sulfide corrosion in heat exchangers at a number of units (Ref 46, 47).

Hydrogen Chloride. In refineries, corrosion by hydrogen chloride is primarily a problem in crude distillation units and, to a lesser degree, in reforming and hydrotreating units. In petrochemical plants, hydrogen chloride contamination can be present from certain feed stocks (from inorganic salts or organic chlorides from chlorinated solvent contamination) or can be formed by the hydrolysis of aluminum chloride catalyst.

In most production wells, chloride salts are found either dissolved in water, that is, emulsified in crude oil, or as suspended solids. Salts also originate from brines injected for secondary recovery or from seawater ballast in marine tankers. Typically, the salts in crude oils consist of 75% sodium chloride, 15% magnesium chloride, and 10% calcium chloride (Ref 48). When crude oils are charged to crude distillation units and heated to temperatures above approximately 120 °C (250 °F), hydrogen chloride is evolved from magnesium and calcium chloride, while sodium chloride is essentially stable up to roughly 760 °C (1400 °F). Hydrogen chloride evolution takes place primarily in crude preheat furnaces. Dry hydrogen chloride, especially in the presence of large amounts of hydrocarbon vapor or liquid, is not corrosive to carbon steel (Ref 49).

When steam is added, however, to the bottom of the crude tower to facilitate fractionation, dilute hydrochloric acid forms in the top of the tower and in the overhead condensing system. Severe aqueous chloride corrosion of carbon steel components can occur upon cooling at temperatures below the initial water dewpoint (Ref 50). Corrosion rate increases with a decrease in pH value of overhead condensate

water. Corrosion is mostly in the form of droplet-impingement attack at elbows of the overhead vapor line and at inlets of overhead condensers. Corrosion also occurs on condenser tubes that are at the temperatures where most of the water condenses out. Often, droplets of hydrochloric acid become entrapped and concentrate under deposits that are present on tower trays, in condenser shells, and at baffles. The resultant underdeposit corrosion is highly localized and usually quite severe.

Overhead condensing systems of both the crude and vacuum towers of crude distillation units are generally made from carbon steel. Coolers and condensers in cooling-water service usually use admiralty metal (C44300) tubes to reduce corrosion and fouling on the water side. Where aqueous chloride corrosion is a problem on the process side, Ti-grade 2 (R50400) tubes should be considered. The top of the crude tower can be lined with alloy 400 (N04400), and tray components made from alloy 400 (N04400) can be used for the upper five or so trays to combat aqueous chloride corrosion. Alloy 400 (N04400) tubes usually have not been cost-effective in overhead coolers and condensers, but alloy 400 (N04400) has been successfully used for selective strip lining of those areas of the overhead system where excessive corrosion occurs despite the implementation of other corrosion control measures.

To minimize aqueous chloride corrosion in the overhead system of crude towers, it is best to keep the salt content of the crude oil charge as low as possible, preferably below 1 pound per thousand barrels (PTB), corresponding to roughly 4 ppm. This is done by proper tank-settling, desalting, or, if necessary, double desalting (Ref 51–53). Another way to reduce overhead corrosion would be to inject a caustic solution of sodium hydroxide into the crude oil downstream of the desalter. Up to 3 PTB (10 ppm) caustic can usually be tolerated from a process point of view, while higher concentrations increase fouling of crude preheat exchangers, boiler corrosion by sodium vanadate (when reduced crude is burned as boiler fuel), or coking in lines and heaters of coking units (Ref 54). Caustic should not be used when reduced crude is charged directly to catalytic cracking or hydrotreating units because of possible catalyst deactivation.

Neutralizers are also injected into the overhead vapor line of the crude tower to maintain the pH value of stripping steam condensate between 5 and 6 (Ref 55–58). A pH value above 7 can increase corrosion with sour crudes, as well as fouling and underdeposit corrosion by neutralizer chloride salts. Where fouling becomes a problem, water should be injected, either intermittently or continuously, to dissolve salt deposits in those areas of the overhead system that are not exposed to stripping-steam condensate (Ref 59). Filming-amine corrosion inhibitors can be injected into the overhead vapor line to provide additional insurance against excessive corrosion (Ref 60–62).

In the downstream refining equipment, chlorides accelerate corrosion by penetrating protective surface films, increasing electrolyte conductivity, or complexing with steel surfaces (Ref 63). In reforming units, organic chlorides are often used to regenerate reformer catalyst. Hydrogen chloride is stripped off the catalyst if excessive moisture is present in the reformer feed; this causes increased corrosion, not only in reforming units but also in hydrotreating units that use excess hydrogen (make-gas) from the reformer. As in the case of crude distillation units, water washing and injection of neutralizers and/or filming-amine corrosion inhibitors can be used to control fouling and corrosion by chloride salts. Hydrogen make-gas can be passed through a water scrubber to remove hydrogen chloride. Selective alloying with alloy 825 (N08825), alloy 400 (N04400), or Ti-grade 2 (R50400) can be required to control chloride attack in heat exchangers and separator drums.

Nitrogen Compounds. Organic nitrogen compounds, such as indole, carbazole, pyridine, or quinoline, are present in many crude oils but do not contribute to corrosion problems unless converted to ammonia or hydrogen cyanide in refining processes (Ref 64). This occurs primarily in catalytic cracking, hydrotreating, and hydrocracking operations where ammonia and hydrogen cyanide, in combination with H_2S and other constituents, become the major constituents of sour water that can be highly-corrosive to carbon steel (Ref 65). Furthermore, this corrosive combination can also result in severe hydrogen charging of steel equipment, resulting in high susceptibility to wet H_2S cracking (i.e., SSC, HIC, and SOHIC). These are discussed in greater detail in the following section, "Sour Water," in this article.

Ammonia is also produced in ammonia plants to become a raw material for the manufacture of urea and other nitrogen-base fertilizers. Ammonia in synthesis gas at temperatures between 450 and 500 °C (840 and 930 °F) causes nitriding of steel components. When synthesis gas is compressed to up to 34.5 MPa (5000 psig) prior to conversion, corrosive ammonium carbonate is formed, requiring various stainless steels for critical components. Condensed ammonia is also corrosive and can cause SCC of stressed carbon steel and low-alloy steel components (Ref 66).

Sour Water. The term *sour water* denotes various types of process water containing primarily H_2S , ammonia, and hydrogen cyanide, often in combination with certain organic compounds, including phenols, mercaptans, and possibly inorganic compounds such as chlorides and fluorides. Sour waters are removed from processed hydrocarbons in refining units by settling in overhead reflux drums, separator drums, water coalescer drums, and other specialized equipment. Depending on their exact composition, sour waters can become highly corrosive, and, under certain circumstances, they even create conditions of turbulent multiphase flow. Consequently, alloy selection and operational

limits of sour water systems need to be carefully considered for specific unit operating conditions. Recently, a joint industry program conducted a significant research effort on sour water (ammonium bisulfide) corrosion, examining the interrelationship between many variables common to refinery sour water systems (Ref 5).

Sour water corrosion is of particular concern in the vapor recovery (light ends) section of catalytic cracking units and in reactor effluent and light ends sections of hydrotreating and hydrocracking units, in which high concentrations of ammonia can saturate process water with ammonium bisulfide and cause serious corrosion of carbon steel components. Furthermore, the combination of ammonium bisulfide with cyanides produced in the hydrocracking process can result in extremely corrosive conditions. The presence of cyanide complexes normally protective sulfide films, leading to accelerated corrosion.

Ammonium bisulfide will also rapidly attack admiralty metal (C44300) tubes and can also corrode nickel-copper alloys such as alloy 400 (N04400). Sour water corrosion is a major problem in some sour water stripping units, in which exceptionally high concentrations of ammonium bisulfide build up in the thin film of condensed water on overhead condenser tubes. The resultant corrosion can be so severe that even tubes made from conventional austenitic stainless steels are attacked. Currently, there has been use of duplex stainless and high-alloyed austenitic stainless steels with PREN values from 30 to over 40, depending on the anticipated severity of the environment. In some cases, Ti-grade 2 (R50400) tubes have been used to provide sufficient resistance for use in this service. The results of the previously mentioned joint industry research program on sour water corrosion have developed a list of alloys and their relative resistance to various sour water conditions. This work has identified the key process conditions and defined limits for commonly used alloys through a combination of experimental (chemical) simulation and flow modeling to relate the data to refinery systems involving multiphase and balanced/imbalanced flow conditions (Ref 5).

Normally, all components in the vapor recovery (light ends) sections of catalytic cracking units are made of carbon steel. Exceptions to this rule include tower internals made of type 405 (S40500) or 410 (S41000) stainless steel and tubes in overhead condensers and compressor aftercoolers made from admiralty metal (C44300), alloy 400 (N04400), or Ti-grade 2 (R50400). Corrosion problems of carbon steel components are often closely associated with hydrogen blistering or other forms of wet H_2S cracking, because sulfide corrosion liberates atomic hydrogen that can diffuse into the steel. Admiralty metal (C44300) tubes in overhead condensers may typically last only 5 years, with leaks finally occurring as a result of ammonia SCC. Depending on the particular process conditions, admiralty metal (C44300) tubes can also

corrode by severe localized attack. Admiralty metal (C44300) tubes in compressor aftercoolers are often replaced with Ti-grade 2 (R50400) tubes or other materials.

Perhaps the biggest recurring problems in sour water systems have been corrosion, hydrogen blistering, and hydrogen cracking phenomena such as HIC, SOHIC, and SSC of carbon steel in coolers, separator drums, absorber/stripper towers, and, occasionally, overhead condensers at a number of locations. These are discussed in greater detail in the section "Environmentally Assisted Cracking (SCC, HEC, and Other Mechanisms)" in this article.

Components in hydrotreating and hydrocracking units that operate at temperatures below approximately 260 °C (500 °F) are typically made from carbon steel. Where aqueous ammonium bisulfide corrosion becomes a problem, generous corrosion allowances may have to be provided for carbon steel (Ref 67, 68). Selective use of duplex stainless steels, such as alloy 2205 (S31803) and alloy 2507 (S32750), superaustenitic stainless steels, such as alloy AL6XN (N08367), alloy 825 (N08825), alloy C-276 (N10276), alloy 400 (N04400), or Ti-grade 2 (R50400) may be required for heat exchangers and separator drums to control excessive corrosion. On some units, corrosion of steel components is accompanied by hydrogen blistering and cracking. Hydrotreating and hydrocracking units that experience fouling problems due to ammonium sulfide or ammonium chloride deposition may require intermittent or continuous water injection (i.e., water washing) to dissolve these salt deposits and reduce the concentration of these constituents. It is of prime importance, however, that sufficient coalescer capacity be available or provided in order to ensure that the injected water is removed. Otherwise, serious corrosion can occur when the water ends up in downstream equipment.

All equipment and piping of reforming units that operate at below approximately 260 °C (500 °F) are usually made from carbon steel. Although admiralty metal (C44300) tubes are often used in water-cooled effluent coolers and condensers, the presence of chlorides may necessitate the selective use of Alloy 400 (N04400) or Ti-grade 2 (R50400). In some cases, carbon steel tubes are superior to admiralty metal (C44300) tubes, provided the cooling water is properly treated. Similar considerations apply to water-cooled coolers and condensers in the overhead systems of prefractionator, splitter, debutanizer, and other fractionation towers. Filming-amine corrosion inhibitors can be used to help control overhead corrosion of steel components.

The principal material of construction for sour water stripping units is carbon steel. There are several varieties of sour water strippers, but nonacidified condensing and noncondensing strippers are most commonly used (Ref 69, 70). The stripping medium is primarily steam. Stripper towers are generally made from carbon steel

with type 316 (S31600) stainless steel, aluminum, or carbon steel internals, depending on corrosion experience. To control tower corrosion, a minimum top temperature of 80 °C (180 °F) is required. Below this temperature, H₂S will concentrate in the upper part of the tower but will not be carried overhead. Feed charge pumps are usually made from cast iron or cast steel, including the impellers. Feed piping, bottoms piping, and the feed/bottoms heat exchanger can be made from carbon steel. Carbon steel has also been satisfactory for stripper reboilers that may be used instead of live stripping steam. Thermosyphon reboilers (with sour water in the tubes) are recommended over kettle reboilers because the latter are often prone to fouling and resultant underdeposit corrosion.

Most corrosion problems have been in overhead condensers of condensing sour water strippers (Ref 71). Although a variety of alloys have been used for overhead condenser tubes, only aluminum and Ti-grade 2 (R50400) can be relied on to provide adequate resistance to the highly corrosive conditions encountered in many overhead systems. Carbon steel is usually satisfactory for the overhead vapor line, condenser shell, rundown lines, accumulator drum, and reflux lines. All welds in these components should be postweld heat treated to avoid SSC or related cracking problems. Reflux pumps can be made of carbon steel or type 304 (S30400) stainless steel, but for optimal performance, alloy 20 (N08020) is recommended. Hydrogen blistering often accompanies corrosion in overhead condenser shells and reflux drums. Water-soluble filming-amine corrosion inhibitors can be injected into the overhead vapor line to help control both corrosion and hydrogen blistering. Few, if any, corrosion problems have been experienced with noncondensing sour water strippers.

Serious sour water corrosion of carbon steel components can occur in the overhead system of amine regenerators (strippers) of gas-treating or sulfur recovery units, especially if all of the water condensate is returned to the tower as reflux. Corrosion is usually accompanied by hydrogen blistering or cracking. Continuous or periodic blowdown of sour water to the sour water stripping unit should be employed to lower the concentrations of H₂S, ammonia, and cyanide in the overhead water condensate. If this fails to control corrosion, carbon steel condenser tubes may have to be replaced with Ti-grade 2 (R50400) tubes. In addition, corrosion can be minimized by operating the regenerator so that roughly 0.5% amine is taken overhead to act as a corrosion inhibitor.

Polythionic Acids. Combustion of H₂S in refinery flares can produce polythionic acids of the type H₂S_xO_y (including sulfurous acid) and cause severe intergranular corrosion of flare tips made of stainless steels and high-nickel alloys (Ref 72). Corrosion can be minimized by using nickel alloys, such as alloy 825 (N08825) or alloy 625 (N06625). Polythionic acids also cause SCC during shutdown, as discussed in

the section "Environmentally Assisted Cracking (SCC, HEC, and Other Mechanisms)" in this article.

Low-Temperature Corrosion by Process Chemicals

Severe corrosion problems can be caused by process chemicals, such as various alkylation catalysts, certain alkylation by-products, organic acid solvents used in certain petrochemical processes, hydrogen chloride stripped off reformer catalyst, and caustic and other neutralizers that, ironically, are added to control acid corrosion. Filming-amine corrosion inhibitors can be quite corrosive if injected undiluted (neat) into a hot vapor stream. Other process chemicals that can be corrosive, or become corrosive depending on the application, are amine solvents used in treating and gas-scrubbing operations.

Acetic Acid. Corrosion by acetic acid can be a problem in petrochemical process units used for the manufacture of certain organic intermediates, such as terephthalic acid. Various types of austenitic stainless steels are used. Nickel-base alloys such as alloy C-4 (N06455) and alloy C-276 (N10276), or titanium, are used to control corrosion by acetic acid in the presence of small amounts of hydrogen bromide or hydrogen chloride.

As a rule, even tenths of a percent of water in acetic acid can have a significant influence on corrosion. Type 304 stainless steel (S30400) usually has sufficient resistance to the low concentrations of acetic acid up to the boiling point. Higher concentrations can also be handled by type 304 stainless steel (S30400) if the temperature is below approximately 90 °C (190 °F). Increasing the chromium and/or nickel content has little effect on resistance to acetic acid. Addition of molybdenum in combination with nickel and chromium in stainless steel, however, markedly increases the resistance of these materials. Consequently, type 316 (S31600) and type 317 (S31700) stainless steels with approximately 2 to 4% Mo in combination with nickel and chromium are used for the overwhelming majority of hot acetic acid applications. Corrosion by acetic acid increases with temperature. Bromide and chloride contamination causes pitting and SCC, while addition of oxidizing agents, including air, can reduce corrosion rates by several orders of magnitude.

Aluminum Chloride. Certain refining and petrochemical processes, such as butane isomerization, ethylbenzene production, and polybutene production, use aluminum chloride as a catalyst (Ref 73). Aluminum chloride is not corrosive if it is kept absolutely dry. If traces of water or water vapor are present in hydrocarbon streams, aluminum chloride hydrolyzes to hydrochloric acid, which can, of course, be highly corrosive. To control corrosion in the presence of aluminum chloride, the feed is dried in calcium chloride dryers. During shutdowns, equipment should be opened for the shortest

possible time. Upon closing, it should be dried with hot air, followed by inert gas blanketing. Equipment that is exposed to hydrochloric acid may require extensive lining with nickel alloys, such as alloy 400 (N04400), alloy B-2 (N10665), alloy B-3 (N10675), alloy C-4 (N06455), or alloy C-276 (N10276) (Ref 74).

Organic chlorides in crude oils will form various amounts of hydrogen chloride at the elevated temperatures of crude preheat furnaces, depending on the chlorides involved. Many "opportunity" crude oils contain small amounts of organic chlorides (5 to 50 ppm) naturally or through contamination with chlorinated organic solvents prior to receipt at the refinery. A major problem also exists due to contamination with organic chloride solvents during production. Although major producers are aware of the problem, some operators may still use chlorinated organic solvents to remove wax deposits in oil field tankage and associated equipment and piping. Spent solvent is then simply added to the crude oil. These solvents are also extensively used for metal-degreasing operations in and out of the refinery, but to a lesser extent in recent years due to environmental control. The problem is that spent solvent can be discarded with slop oil, which is added to the crude oil and charged to the crude distillation unit.

Contaminated crude oils have been found to contain as much as 7000 ppm chlorinated hydrocarbons. Such crude oils not only cause severe corrosion in the overhead system of crude distillation towers but also affect reformer operations (Ref 75). Typical process and operational problems in the latter category include runaway cracking, rapid coke accumulation on the catalyst, and increased corrosion in fractionator overhead systems (Ref 76, 77). Obviously, every effort must be made to avoid charging contaminated crude oil. Organic chlorides cannot be removed by desalting. If contaminated crude oil must be run off, the usual approach is to blend it slowly in very limited amounts into uncontaminated crude oil at levels that will not cause these problems.

Hydrogen Fluoride. Some alkylation processes use concentrated hydrofluoric acid instead of sulfuric acid as the catalyst. In general, hydrofluoric acid is less corrosive than hydrochloric acid because at high concentrations, it passivates steel by the formation of protective fluoride films. If these films are destroyed by diluted acid, impurities, or flow-induced turbulence, extremely severe corrosion occurs. Therefore, as long as feed stocks are kept dry, carbon steel—with various corrosion allowances—can be used for vessels, piping, and valve bodies of hydrofluoric acid alkylation units. Alloy 400 (N04400) is used selectively at locations where excessive corrosion has been experienced. A related problem to corrosion in hydrofluoric acid is the associated generation of atomic hydrogen. Absorption of atomic hydrogen can result in hydrogen blistering and cracking of carbon steel equipment and cracking of hardened bolts (Ref 78).

By following proper design practices and prescribed maintenance procedures and by diligently keeping feeds stocks and equipment dry, there will be few corrosion problems. All carbon steel welds that contact hydrofluoric acid should be postweld heat treated (Ref 79). This applies especially to welds in various vessels. Vessels should be radiographed to check for slag inclusions in plates and welds; slag inclusions are preferentially attacked by hydrofluoric acid. Hydrofluoric acid has the capability of finding leak paths via weld inclusions and porosity or threads. During welding, each preceding pass must be properly cleaned. All threaded connections should be seal welded. Where leaks do show up after start-up, small holes can often be peened shut, or small bits of copper or lead can be peened into larger holes to seal a leak. Any subsequent repair welds should also be postweld heat treated.

Fractionation towers should have type 410 (S41000) stainless steel tray valves and bolting; alloy 400 (N04400) tray valves and bolting are preferred for the deisobutanizer tower. The acid rerun tower usually requires cladding with alloy 400 (N04400) and alloy 400 (N04400) tray components. To avoid SCC, alloy 400 (N04400) welds that contact hydrofluoric acid should be postweld heat treated. No asbestos or wicking gaskets should be used on trays. Soft iron gaskets are used on channel head-to-shell joints of heat exchangers. Spiral-wound alloy 400/synthetic fluorine-containing resin gaskets are also used but are more expensive. Carbon steel U-tube bundles are preferred for all exchangers that contact hydrofluoric acid; alloy 400 (N04400) tubes have been found to offer few advantages (Ref 80). Tube ends and tubesheet holes should be carefully cleaned to ensure that rolled tube joints will be tight against hydrofluoric acid. Seal welding of tubes may be required. Internal bolting should not be used in exchangers.

The piping is generally carbon steel with welded connections that have received postweld heat treatment. All taps should be self-draining and should have double block valves. Instrument connections should be made from the top. Valve bodies on gate and plug valves are usually carbon steel, with synthetic fluorine-containing resin packing and seats. Relief valves should have alloy 400 (N04400) trim. Synthetic fluorine-containing resin tape sealing should be used on any threaded connections. Pumps in hydrofluoric acid service normally have carbon steel casings that are weld overlaid with alloy 400 (N04400). Impellers and sleeves should be alloy 400 (N04400); shafts should be alloy K-500 (N05500).

Specific areas where corrosion is likely to occur include the bottom of the acid rerun tower, the feed inlet areas of the deisobutanizer and depropanizer towers, the overhead condensers of these towers, the reboiler of the propane stripper, and piping around the acid rerun tower (Ref 81). Trouble areas in vessels are often selectively strip lined with alloy 400 (N04400). Dimpling of tray valve caps during manufacture

reduces their tendency to stick to trays because of corrosion products. Alloy 400 (N04400) piping is used to replace carbon steel piping, which corrodes at excessive rates; welds should be postweld heat treated.

Experience has shown that most corrosion problems in hydrofluoric acid alkylation units occur after shutdowns, because pockets of water have been left in the equipment. This water is from the neutralization and washing operation required for personnel safety before the equipment can be opened for inspection. It is very important that equipment be thoroughly dried by draining all low spots and by circulating hydrocarbon before the introduction of hydrofluoric acid catalyst at start-up. Corrosion by hydrofluoric acid is occasionally accompanied by hydrogen blistering or cracking. Filming-amine corrosion inhibitors have been injected into the overhead systems of various towers, sometimes in conjunction with injection of dilute soda ash solutions. Because the primary goal of proper operations is to keep the unit as dry as possible, intentional addition of water in any form should be considered only as a last resort.

Sulfuric Acid. Certain alkylation units use essentially concentrated sulfuric acid as the catalyst; some of this sulfuric acid is entrained in reactor effluent and must be removed by neutralization with caustic and scrubbing with water. Acid removal may not be complete, however, and traces of acid—at various concentrations (in terms of water)—remain in the stream. Sulfuric acid can be highly corrosive to carbon steel, which is the principal material of construction for sulfuric acid alkylation units. Because the boiling point of sulfuric acid ranges from 165 to 315 °C (330 to 600 °F), depending on concentration, entrained acid usually ends up in the bottom of the first fractionation tower and reboiler following the reactor; this is where the entrained acid becomes concentrated.

Acid concentrations above 85% by weight are usually not corrosive to carbon steel if temperatures are below 40 °C (100 °F). Cold-worked metal (usually bends) should receive thermal stress relief. Under ideal operating conditions, few, if any, corrosion and fouling problems occur (Ref 82, 83).

Carbon steel depends on a film of iron sulfate for corrosion resistance, and if its film is destroyed by high velocities and flow turbulence, corrosion can be quite severe. For this reason, flow velocities should be below 1.2 m/s (4 ft/s). Attack in the form of erosion-corrosion can occur at piping welds that have not received postweld heat treatment. This highly localized attack immediately downstream of piping welds has been attributed to a spheroidized structure affected by the heat of welding; a normalizing postweld heat treatment at 870 °C (1600 °F) is required to minimize this type of corrosion (Ref 84). Velocity-accelerated corrosion can also be a problem at locations of high turbulence or velocity (Ref 85). Alloy 20 (N08020)

is more resistant than carbon steel to this type of corrosion. In extreme cases, however, even alloy 20 (N08020) will be damaged by erosion-corrosion, and the selective use of alloy B-2 (N10665) and alloy B-3 (N10675) may be required.

Carbon steel valves usually require alloy 20 (N08020) internals or trim, because even slight attack of carbon steel seating surfaces is sufficient to cause leakage (Ref 86). Pump internals and injection and mixing nozzles in concentrated or spent sulfuric acid service are often made of alloy 20 (N08020), alloy B-2 (N10665), and alloy C-4 (N06455) or alloy C-276 (N10276). For hydrocarbon streams containing only traces of concentrated or dilute sulfuric acid, steel-body valves with type 316 (S31600) stainless steel trim can be used. In this service, steel pump casings that are weld overlaid with aluminum bronze have been successfully used. Pump impellers made from high-silicon cast iron are often used.

Piping for hydrocarbon/acid mixing lines ahead of the reactors may require alloy 20 (N08020), because water contamination of feed stocks can cause severe corrosion of carbon steel. Alloy 400 (N04400) has been found to be useful for reactor effluent lines around the caustic and wash-water injection points. Valve trays in fractionation towers require type 405 (S40500) or type 410 (S41000) stainless steel tray valves and bolting. In general, organic coatings are not resistant to concentrated sulfuric acid. Synthetic fluorine-containing resin has excellent resistance to sulfuric acid and is extensively used in gaskets, pump valve packing, and mixing nozzles.

In addition to sulfuric acid, reactor effluent contains traces of alkyl and dialkyl sulfates from secondary alkylation reactions (Ref 87). These esters decompose in reboilers to form sulfur dioxide and polymeric compounds (the latter are notorious foulants). Sulfur dioxide combines readily with water in the upper part and overhead system of fractionation towers; the resultant sulfurous acid can cause severe corrosion in overhead condensers. In some units, carbon steel or admiralty metal (C44300) tubes in overhead condensers, particularly those of the deisobutanizer tower, may have to be replaced with alloy 400 (N04400) or Ti-grade 2 (R50400) tubes. As a rule, however, titanium is not resistant to sulfuric acid corrosion. It can be used only under limited acid concentration and/or in the presence of oxidizing or inhibitive agents. Neutralizers can be injected into the overhead vapor lines of various towers to maintain the pH value of aqueous condensate near 7. Filming-amine corrosion inhibitors can also be injected.

Caustic. Sodium hydroxide is widely used in refinery and petrochemical plant operations to neutralize acidic constituents. At ambient temperature and under dry conditions, caustic can be handled in carbon steel equipment. Carbon steel is also satisfactory for aqueous caustic solutions between 50 and 80 °C (120

and 180 °F), depending on concentration. For caustic service above these temperatures but below approximately 95 °C (200 °F), carbon steel can also be used if it has been postweld heat treated to avoid SCC at welds. Austenitic stainless steels, such as type 304 (S30400), can be used up to approximately 120 °C (250 °F), while nickel alloys are required at higher temperatures. Figure 3 is the caustic soda serviceability chart that indicates the concentration and temperature limits for various materials in caustic service (Ref 88).

Severe caustic corrosion of the crude transfer line, which is immediately downstream of the caustic injection point, can occur in crude distillation units when 40% (by weight) caustic solution is injected into hot, desalted crude oil to neutralize any remaining hydrogen chloride. Predilution of the caustic with water to form a 3% (by weight) solution minimizes this problem. Better dispersion of the more diluted solution in the hot crude oil prevents local concentration and puddles of molten caustic from collecting along the bottom of the transfer line, which can result in corrosion and SCC problems. If caustic is injected too close to an elbow of the transfer line, impingement by droplets of caustic can also cause severe attack and hole-through at the elbow.

There are some unusual situations in which caustic corrosion is encountered. For example, traces of caustic can become concentrated due to local boiling or evaporation in boiler feed water and cause corrosion (gouging) and SCC (caustic embrittlement). This occurs in boiler tubes that alternate between wet and dry conditions (steam blanketing) because of overfiring. In some petrochemical processes, caustic gouging is found under deposits in heat exchangers that remove heat by generation of steam. For example, vertical heat exchangers for cracked gas in ethylene units are especially vulnerable

if deposits are allowed to accumulate on the bottom tubesheet. Boiler feed water permeates these deposits and evaporates, and this causes the caustic to concentrate in any liquid that is left behind. The caustic content of such trapped liquid can reach several percent, which is sufficient to break down the normally protective iron oxide (magnetite) film on boiler steel and can easily result in severe caustic corrosion.

Amine Solvents and Neutralizers. Corrosion of carbon steel by amines in gas-treating and sulfur recovery units can usually be traced to faulty plant design, poor operating practices, and solution contamination (Ref 89). In general, corrosion is most severe in systems removing only carbon dioxide and is least severe in systems removing only H₂S. Systems handling mixtures of the two fall between these two extremes if the gases contain at least 1 vol% H₂S. Corrosion in amine plants using monoethanolamine is usually more severe than in those using diethanolamine, because the former is more prone to degradation and the formation of heat-stable salts at high temperatures.

The most common forms of corrosion in amine solvents is not directly caused by the amine itself but is caused by dissolved H₂S or carbon dioxide and by the amine degradation products (Ref 90). Corrosion is most severe at locations where acid gases are desorbed or removed from rich-amine solution. Here, temperatures along with tendencies for flow turbulence (i.e., locally high wall shear stress) and local flashing of the gas are highest. This includes the regenerator (stripper) reboiler and lower portions of the regenerator itself (Ref 91). Corrosion can also be a significant problem on the rich-amine side of the lean/rich-amine exchanger, in amine solution pumps, and in reclaimers. Hydrogen blistering has been a problem in the bottom of the contactor (absorber) tower and in regenerator overhead condensers and reflux drums (Ref 92). This has been associated with wet H₂S cracking (versus amine SCC) as a result of the hydrogen generated by H₂S corrosion in the rich-amine solution. These conditions are aggravated by disruption of normally protective sulfide surface films on the steel, which allows accelerated hydrogen charging, leading to crack initiation and propagation.

The common material of construction for amine units is carbon steel. To prevent alkaline SCC, welds of components in both lean- and rich-amine service should be postweld heat treated regardless of service temperature (Ref 93). Postweld heat treatment also protects against hydrogen stress cracking by lowering both the HAZ hardness and residual tensile stresses in the location of the weld. On the whole, there have been relatively few corrosion problems in most amine units. In the most severe cases of corrosion in carbon dioxide removal, new inhibitors have been designed that replace older, more highly toxic formulations based on heavy metals additions (Ref 94).

Limits for corrosion control, including amine concentration (approximately 20%), acid gas

loading (0.3 to 0.6 mole/mole), flow rate (rich amine, 1.8 m/s, or 6 ft/s; lean amine, 1.8 to 6 m/s, or 6 to 20 ft/s), rich circuit temperatures (100 to 105 °C, or 212 to 220 °F), and reboiler temperatures (125 to 150 °C, or 260 to 300 °F), have been developed by evaluating services experienced in various plants with sometimes vastly different designs, throughput, and operating conditions (Ref 95–98). Also, limits for impurities such as heat-stable salts are typically based entirely on experience and may range from 1 to 2%. Consequently, there is a wide operating envelope with little technical basis to help designers and operators optimize unit reliability and performance. There has been only limited use of test data, and none has approached this area using rigorously controlled environment and flow conditions. New studies are in progress under joint industry sponsorship that are investigating the interactions between chemical and flow conditions in amine solvents, which should be available in the coming years. This work includes monoethanolamine, diglycolamine, and diethanolamine as well as parametric effects of temperature, CO₂/H₂S ratio, heat-stable salts, and organic acids (Ref 99).

Sidestream filtration is also extremely beneficial. Filming-amine corrosion inhibitors are often ineffective. Several proprietary oxidizing corrosion inhibitors based on sodium metavanadate are available. These have been successfully used in certain cases, but licensing costs tend to be high for any but the smaller units.

Regenerator towers usually should be lined with type 405 (S40500) stainless steel, and tower internals are often made of type 304 (S30400) stainless steel. Where applicable, type 304 (S30400) stainless steel is required for the rich-amine pressure of the let-down valve, as well as for piping downstream of the let-down valve, to control corrosion accelerated by high flow turbulence.

Corrosion in the regenerator reboiler is usually in the form of pitting and groove-type corrosion of tubes and is caused by localized overheating inside baffle holes (Ref 100). If thermosiphon reboilers are undersized, part of the tube bundle will become vapor blanketed, and the tubes will overheat. Subsequent exposure of the hot tubes to amine solution will cause severe turbulence and velocity-accelerated corrosion. Vapor blanketing also occurs if tubes are allowed to fill partially with steam condensate; this reduces the amount of tube surface available for heat transfer and increases the heat flux through the remainder of the tubes. Unless faulty reboiler operation can be corrected, carbon steel tubes may have to be replaced with type 304 (S30400) or type 316 (S31600) stainless steel tubes. Alloy 400 (N04400) reboiler tubes have been successfully used in amine units that handle only carbon dioxide.

As a rule, carbon steel tubes are satisfactory for regenerator overhead condensers. As discussed in the section "Sour Water" in this article, high corrosion rates can occur at this location, and carbon steel tubes may have to be replaced

Fig. 3 Caustic soda service chart for carbon steel, weldments, and nickel alloys. Source: Ref 88

with Ti-grade 2 (R50400) tubes. Carbon steel tubes are used in reclaimers with proper neutralization of acidic constituents (Ref 101). Because the reclaimer can be taken out of service at any time, periodic retubing with carbon steel presents no problems. Cast iron pumps normally are used in low-pressure amine service. If corrosion problems occur, high-silicon cast iron impellers can be used. In high-pressure amine service, type 316 (S31600) stainless steel pumps may be needed.

Phenol (carbolic acid) is used in refineries to convert heavy, waxy distillates obtained by crude oil distillation into lubricating oils. As a rule, all components in the treating and raffinate recovery sections, except tubes in water-cooled heat exchangers, are made from carbon steel. If water is not present, few significant corrosion problems can be expected to occur in these sections. In the extract recovery section, however, severe corrosion can occur, especially where high flow turbulence is encountered. As a result, certain components require selective alloying with type 316 (S31600) stainless steel. Typically, stainless steel liners are required for the top of the dryer tower, the entire phenol flash tower, and various condenser shells and separator drums that handle phenolic water. Tubes and headers in the extract furnace should also be made of type 316 (S31600) stainless steel, with U-bends sleeved with alloy C-4 (N06455) on the outlet side to minimize velocity-accelerated corrosion.

High-Temperature Corrosion

High-temperature corrosion problems in refineries are of considerable importance (Ref 102). Equipment failures can have serious consequences, because processes at high temperatures usually involve high pressures as well. With hydrocarbon streams, there is always the danger of fire when ruptures occur. On a more positive note, high-temperature refinery corrosion is primarily caused by various sulfur compounds originating with crude oil. Over the years, extensive research has been done to establish the mechanism of various forms of high-temperature sulfidic corrosion. Corrosion rate correlations are available; therefore, equipment life can be predicted with some degree of reliability.

Sulfidic Corrosion. Corrosion by various sulfur compounds at temperatures between 260 and 540 °C (500 and 1000 °F) is a common problem in many petroleum refining processes and, occasionally, in petrochemical processes. Sulfur compounds originate with crude oils and include polysulfides, H₂S, mercaptans, aliphatic sulfides, disulfides, and thiophenes (Ref 103) and are commonly found in concentrations of 0.1 to over 5% total sulfur. Sulfur compounds react with metal surfaces at elevated temperatures, forming metal sulfides, certain organic molecules, and H₂S (Ref 104, 105). The relative corrosivity of sulfur compounds generally increases with temperature. Additionally, the higher the

temperature, the more likely it is that larger and more stable organic sulfides break down into reactive components that can become involved in the corrosion process. Depending on the process particulars, corrosion is in the form of uniform thinning, localized attack, or erosion-corrosion. Corrosion control depends almost entirely on the formation of protective metal sulfide scales that exhibit parabolic growth behavior (Ref 106). In general, nickel and nickel-rich alloys (without chromium or other similar alloying additions) are rapidly attacked by sulfur compounds at elevated temperatures, while chromium-containing steels and alloys provide excellent corrosion resistance (as do additions of aluminum). The combination of H₂S and hydrogen can be particularly corrosive, and, as a rule, austenitic stainless steels are required for effective corrosion control.

Sulfidic Corrosion without Hydrogen

Present. This type of corrosion occurs primarily in various components of crude distillation units, catalytic cracking units, and hydrotreating and hydrocracking units upstream of the hydrogen injection line. Crude oil distillation units that process mostly sweet crude oils (less than 0.6% total sulfur, with essentially no H₂S) experience relatively few corrosion problems. Preheat-exchanger tubes, furnace tubes, and transfer lines are generally made from carbon steel, as is corresponding equipment in the vacuum distillation section. The lower shell of distillation towers, where temperatures are above 230 °C (450 °F), is usually lined with stainless steel containing 12% Cr, such as type 405 (S40500). This prevents impingement attack under the highly turbulent flow conditions encountered, for example, near downcomers. For the same reason, trays are made of stainless steel containing 12% Cr. Even with low corrosion rates of carbon steel, certain tray components, such as tray valves, may fail in a short time, because attack occurs from both sides of a relatively thin piece of metal.

Crude distillation units that process mostly sour crude oils that result in evolution of high concentrations of H₂S during distillation require additional alloy protection against high-temperature sulfidic corrosion. The extent of alloying needed also depends on the design and the operating practices of a given unit. Typically, such units require low-alloy steels containing a minimum of 5% Cr for furnace tubes, headers and U-bends, and elbows and tees in transfer lines. In vacuum furnaces, tubes made from chromium steels containing 9% Cr are often used. Distillation towers for processing sulfidic crudes are usually made from similar materials as those of units that process mostly sweet crude oils. Where corrosion problems persist, upgrading with steels containing a greater amount of chromium is indicated.

The high processing temperatures encountered in the reaction and catalyst regeneration section of catalytic cracking units require extensive use of refractory linings to protect all carbon steel components from oxidation and

sulfidic corrosion. Refractory linings also provide protection against erosion by catalyst particles, particularly in cyclones, risers, standpipes, and slide valves. Stellite hardfacing is used on some components to protect against erosion. When there are no erosion problems and when protective linings are impractical, austenitic stainless steels, such as type 304 (S30400), can be used. Cyclone dip legs, air rings, and other internals in the catalyst regenerator are usually made from type 304 (S30400) stainless steel, as is piping for regenerator flue gas. Reactor feed piping is made from low-alloy steel, such as 5Cr-0.5Mo or 9Cr-1Mo, to control high-temperature sulfidic corrosion.

The main fractionation tower is usually made of carbon steel, with the lower part lined with stainless steel containing 12% Cr, such as type 405 (S40500) (Ref 107). Slurry piping between the bottom of the main fractionation tower and the reactor may receive an additional corrosion allowance as protection against excessive erosion. As a rule, there are few corrosion problems in the reaction, catalyst regeneration, and fractionation sections (Ref 108).

Hydrocracking and hydrotreating units usually require alloy protection against both high-temperature sulfidic corrosion and high-temperature hydrogen attack (Ref 109, 110). Low-alloy steels may be required for corrosion control ahead of the hydrogen injection line.

The so-called McConomy curves can be used to predict the relative corrosivity of crude oils and their various fractions (Ref 111). Although this method relates corrosivity to total sulfur content, and thus does not take into account the variable effects of different sulfur compounds, it can provide reliable corrosion trends if certain corrections are applied. Plant experience has shown that the McConomy curves, as originally published, tend to predict excessively high corrosion rates. The curves apply only to liquid hydrocarbon streams containing 0.6 wt% S (unless a correction factor for sulfur content is applied) and do not take into account the effects of vaporization and flow regime. These conditions are typically related to the very high wall shear stress conditions that can occur in certain multiphase flow regimes (e.g., slug flow and droplet impingement). In these cases, either the local liquid turbulence or impact of liquid droplets can produce accelerated corrosion as a result of their mechanical influence (e.g., erosion or fracturing) on normally protective corrosion scales. The curves can be particularly useful, however, for predicting the effect of operational changes on known corrosion rates.

Over the years, it has been found through service experience that corrosion rates predicted by the original McConomy curves should be decreased by a factor of roughly 2.5, resulting in the modified curves shown in Fig. 4. The curves demonstrate the beneficial effects of alloying steel with chromium in order to reduce corrosion rates. Corrosion rates are roughly halved when the next higher grade of low-alloy steel (for example, 2.25Cr-1Mo, 5Cr-0.5Mo,

7Cr-0.5Mo, or 9Cr-1Mo steel) is selected. Essentially, no corrosion occurs with stainless steels containing 12% or more chromium. Although few data are available, plant experience has shown that corrosion rates start to decrease as temperatures exceed 455 °C (850 °F). Two explanations frequently offered for this phenomenon are the possible decomposition of reactive organic sulfur compounds and the formation of a protective coke layer formed from thermal decomposition of the hydrocarbon species in the oil.

An important consideration in selecting materials is that metal skin temperatures, rather than stream temperatures, should be used to predict corrosion rates when significant differences between the two arise. This can be of major consequence when increasing unit throughput, and higher-than-the-original-designed heat flux results in increased metal skin temperatures. For example, metal temperatures of furnace tubes are typically 85 to 110 °C (150 to 200 °F) higher than the temperature of the hydrocarbon stream passing through the tubes. Furnace tubes normally corrode at a higher rate on the hot side (fire side) than on the cool side (wall side), as shown in Fig. 5. Convective-section tubes often show accelerated corrosion at contact areas with tube hangers because of locally increased temperatures. Similarly, replacement of bare convective-section tubes with finned or studded tubes can further increase tube metal temperatures by 85 to 110 °C (150 to 200 °F). The increased temperature on the hot wall can result in decomposition of more stable sulfur species and increase production of H₂S as well as increase the overall chemical reactivity on the metal surface.

Fig. 4 Modified McConey curves showing the effect of temperature on high-temperature sulfidic corrosion of various steels and stainless steels. Source: Ref 112

Correction factors for process streams with various total sulfur contents, averages of those proposed originally by McConey, are shown in Fig. 6. As can be seen, doubling the sulfur content can increase corrosion rates by approximately 30%. In atmospheric distillation, relatively nonreactive thiophenes are greater in high-boiling cuts (and residuum) than in the original crude charge. Therefore, an additional factor ranging from 0.5 to 1 may have to be applied to the total sulfur content so that realistic corrosion rates can be obtained for such cuts. The degree of vaporization and the resultant two-phase flow regimes can have a significant effect on high-temperature sulfidic corrosion.

Sulfidic Corrosion with Hydrogen Presence. The presence of hydrogen in, for example, hydrotreating and hydrocracking operations, increases the severity of high-temperature sulfidic corrosion. Hydrogen converts organic sulfur compounds in feed stocks to H₂S; corrosion becomes a function of H₂S concentration (or partial pressure).

Downstream of the hydrogen injection line, low-alloy steel piping usually requires aluminizing in order to minimize sulfidic corrosion. Alternatively, type 321 (S32100) stainless steel can be used. Tubes in the preheat furnace are aluminized low-alloy steel, aluminized 12% Cr stainless steel, or type 321 (S32100) stainless steel. Reactors are usually made of 2.25Cr-1Mo steel, either with a type 347 (S34700) stainless steel weld overlay or an internal refractory lining. Reactor internals are often type 321 (S32100) stainless steel (Ref 113).

Depending on the expected corrosion rates, reactor effluent piping operating above approximately 260 °C (500 °F) is made of type 321 (S32100) stainless steel, aluminized low-alloy steel, regular low-alloy steel, or carbon steel with suitable corrosion allowances. When selecting

Fig. 5 High-temperature sulfidic corrosion of 150 mm (6 in.) diameter carbon steel tube from radiant section of crude preheat furnace at crude distillation unit. Note accelerated attack on fire side.

materials for this service, the recommendations of the API should be followed to avoid problems with high-temperature hydrogen attack (Ref 114). The same considerations generally apply to separator drums and heat-exchanger vessels operating at temperatures above 260 °C (500 °F). Type 321 (S32100) stainless steel is usually required for heat-exchanger tubes at these temperatures.

A number of researchers have proposed various corrosion rate correlations for high-temperature sulfidic corrosion in the presence of hydrogen (Ref 115–121), but the most practical correlations seem to be the so-called Couper-Gorman curves. The Couper-Gorman curves are based on a survey conducted many years ago by National Association of Corrosion Engineers (NACE) Committee T-8 (currently designated STG 34) on Refinery Corrosion (Ref 122).

The Couper-Gorman curves differ from those previously published in that they reflect the influence of temperature on corrosion rates throughout a whole range of H₂S concentrations. Total pressure was found not to be a significant variable between 1 and 18 MPa (150 and 2650 psig). It was also found that essentially no corrosion occurs at low H₂S concentrations and temperatures above 315 °C (600 °F), because formation of iron sulfide becomes thermodynamically impossible. Curves are available for carbon steel, 5Cr-0.5Mo steel, 9Cr-1Mo steel, 12% Cr stainless steel, and 18Cr-8Ni austenitic stainless steel. For the low-alloy steels, two sets of curves apply, depending on whether the hydrocarbon stream is naphtha or gas oil. The curves again demonstrate the beneficial effects of alloying steel with chromium to reduce the corrosion rate. Several licensors and major refiners have other methodologies or internally developed data that are used for corrosion prediction and materials selection.

Modified Couper-Gorman curves are shown in Fig. 7 to 14. To facilitate use of these curves,

original segments of the curves were extended (dashed lines). In contrast to sulfidic corrosion in the absence of hydrogen, there is often no real improvement in corrosion resistance unless chromium content exceeds 5%. Therefore, the curves for 5Cr-0.5Mo steel also apply to carbon

steel and low-alloy steels containing less than 5% Cr. Stainless steels containing at least 18% Cr are often required for essentially complete immunity to corrosion. Because the Couper-Gorman curves are primarily based on corrosion rate data for an all-vapor system, partial

condensation can be expected to increase corrosion rates because of droplet impingement.

Recent experience has indicated tendencies for accelerated corrosion rates in piping and reboiler furnace tubes associated with fractionation and distillation units downstream from

hydrotreaters and hydrocrackers (Ref 123). This corrosion was considered unusual, because these units were considered to have low total sulfur and to be generally H_2 -free. In some cases, alloy steels with 5 to 9% Cr corroded at rates similar to carbon steel. This behavior was not predicted by review of the commonly available corrosion prediction curves for sulfidic corrosion. The observations also mentioned that corrosion was most severe at areas of high turbulence, producing elevated wall shear stress resulting from multiphase flow, direction changes (elbows and tees), and in pumps, leading to suppositions that the cause was velocity-accelerated sulfidic attack. Furthermore, the corrosion even occurred with very low (ppm) levels of sulfur species present in the process stream. Some cases involved higher corrosion rates on the top of the tubes (Ref 124).

When selecting steels for resistance to high-temperature sulfidic corrosion in the presence of hydrogen, the possibility of high-temperature hydrogen attack should also be considered. Conceivably, this problem arises when carbon steel and low-alloy steels containing less than 1% Cr are chosen for temperatures exceeding 260 °C (500 °F) and hydrogen partial pressures above 689 kPa (100 psia) and when corrosion rates are expected to be relatively low.

Naphthenic acids are organic acids that are present in many crude oils, especially those from California, Venezuela, Eastern Europe, and Russia. However, newer sources of crude oil with concerns for naphthenic acid corrosion have included those from West Africa, Canada, China, and the North Sea.

The main acids from naphthenic-based crudes are saturated ring structures with a single carboxyl group. Their general formula may be written as $R(CH_2)_nCOOH$, where R is usually a cyclopentane ring. The higher-molecular-weight acids can be bicyclic ($12 < n < 20$), tricyclic ($n > 20$), and even polycyclic (Ref 125, 126). Naphthenic acid content is generally expressed in terms of the neutralization number (total acid number, or TAN), which is determined by titration with potassium hydroxide, as described in ASTM D 664 (Ref 127). The units for TAN are mg KOH in 100 g of oil to bring the solution to neutralization. However, minor amounts of other organic acids can also be present and contribute to the measured acidity of the crude oil using this method. These are commonly fatty acids and phenolic compounds that easily thermally decompose and consequently do not contribute significantly to corrosion in refining operations. An alternative method of determination of TAN values is UOP 565, which first removes acidic contribution from these nonnaphthenic acidic species (Ref 128).

Naphthenic acids are commonly thought to be corrosive only at temperatures above approximately 230 °C (450 °F) in the general range from TAN 1 to 6 encountered with crude oil and various side cuts (hydrocarbon fractions). However, recent experience suggests that the general limits for TAN in whole crudes (producing naphthenic acid corrosion in the refining process) may be as low as 0.3 to 0.5 in the whole crude oil and approximately 1 to 1.5 in the hydrocarbon fractions. This occurs as a result

of fractionation and concentration of the naphthenic acids along with the hydrocarbon species during the refining process. Therefore, a whole crude with a TAN value of 0.5 could produce side cuts with much higher TAN values, with concentrations of 3 to 5 times the whole crude TAN value not uncommon.

At any given temperature, corrosion rate is generally proportional to TAN. Corrosion rate can increase by a factor of 3 with each 55 °C (100 °F) increase in temperature above 230 °C (450 °F). In contrast to high-temperature sulfidic corrosion, no protective scale is formed during naphthenic acid corrosion, and low-alloy steels containing up to 9% Cr provide no benefits whatsoever over carbon steel (Ref 129). Some improvement can be obtained with the use of 12% Cr in some mild-to-intermediate environments. However, at higher TAN levels, even 12% Cr stainless steel is of no benefit, and types 304, 316, or 317 are required to resist naphthenic acid attack. The presence of naphthenic acids may accelerate high-temperature sulfidic corrosion that occurs at furnace headers, elbows, and tees of crude distillation units because of unfavorable flow conditions. A recent survey of literature on naphthenic acid corrosion was published by NACE International in 1999 (Ref 130).

Severe naphthenic acid corrosion has been experienced primarily in the vacuum towers of crude distillation units in the temperature zone of 290 to 345 °C (550 to 650 °F) and sometimes as low as 230 °C (450 °F) (Ref 131). Damage is in the form of pitting and localized (lake-type) attack of tray components and vessel walls. Attack is often limited to the undersides of tray floors and to the inside and very top of the outside surfaces of bubble caps, as shown in Fig. 15. These areas are normally not covered by a layer of liquid, which suggests that the attack was caused by impinging droplets of the condensing acids. No corrosion damage is found at temperatures above 345 °C (650 °F), because of a combination of thermal degradation of the naphthenic acids and the formation of a protective coke layer.

In a recent study (Ref 35), a major investigation of naphthenic acid corrosion was conducted involving a group of major oil companies. It revealed new information about the details of naphthenic acid corrosion and its relationship to flow conditions and sulfur species. This effort characterized naphthenic acids from numerous crude oil sources and found that they varied greatly in terms of their chemical structure (straight chain or one to four ring structures, as shown in Fig. 16), which also resulted in their varying characteristics in terms of fractionation, thermal stability, and corrosivity at various locations in the distillation process. Maximum corrosivity in the temperature range 260 to 345 °C (500 to 650 °F) was associated with naphthenic acids with one and two rings; however, the most thermally stable naphthenic acids were those with three or more rings. Therefore, there could be situations where hydrocarbon

fractions have the same nominal TAN value but could vary in terms of naphthenic acid corrosivity.

Secondly, flow- or turbulence-induced wall shear stress was also a major factor in the severity of naphthenic acid corrosion. A special hot oil flow loop was designed to recreate conditions involved in crude oil refining at flow rates of up to 107 m/s (350 ft/s) producing wall shear stress levels up to 1800 Pa (0.26 psi), typical of partially vaporized, multiphase flow. Over a range of TAN levels, this apparatus was used to map conditions of impingement corro-

sion for 5Cr-0.5Mo (Fig. 17), 9Cr-1Mo (Fig. 18), and 12Cr steels (Ref 35). Through this work, it was determined that there were two different mechanisms that provided the onset of naphthenic acid attack, both of which involved destruction of the normally protective sulfide film that forms on steels in hot crude oil refining environments. At high TAN and low flow velocity, the mechanism involves chemical dissolution of the FeS film by local chemical attack. For this to occur, high TAN levels were required. However, under high velocity or highly turbulent flow, attack can occur at much lower

TAN levels as a result of mechanical fracturing of the protective sulfide film from the high shear stress flow conditions. Figures 19 and 20 show the surface of a 5Cr-0.5Mo steel under high-TAN/low-flow and low-TAN/high-flow conditions, respectively (Ref 35).

Figures 17 and 18 also show the influence of H₂S on the severity of corrosion. These figures show the inhibition of naphthenic acid corrosion on both 5Cr-0.5Mo and 9Cr-1Mo steels at TAN 3.5 and 60 m/s (200 ft/s) by the presence of a H₂S partial pressure of 1.4 kPa (0.2 psia). However, for the same nominal conditions except with a high partial pressure of H₂S—3.1 kPa (0.45 psia)—impingement attack is reestablished for the 5Cr steel but is still inhibited for the 9Cr steel. Presumably, this behavior is because 9Cr-1Mo steel has greater resistance to sulfur than the lower-alloy 5Cr-0.5Mo steel. For conditions free from naphthenic acid (TAN 0) at 60 m/s (200 ft/s), no impingement attack was observed in the 5Cr steel. However, when 3.1 kPa (0.45 psia) H₂S was included in the environment, impingement attack was observed, as was the case at TAN 3.5. Therefore, it was concluded that in the presence of conditions of high sulfur and velocity, the attack was dominated in this material by velocity-accelerated sulfidic corrosion regardless of the TAN level. Furthermore, the role of sulfur and other organic sulfur species on inhibiting naphthenic acid corrosion and other organic sulfur specimens was also examined. As shown in Fig. 21, inhibition occurred over a limited range of H₂S concentration for 9Cr-1Mo steel despite the fact that the sulfur addition was made either as direct H₂S gas or by the presence of an organic sulfur compound. The controlling parameter appears to be how much H₂S is available to participate in the corrosion reaction, which determines the stability of the sulfide film and the ultimate resistance to naphthenic or sulfidic corrosion. This approach indicates that there is actually a continuum between the two mechanisms of corrosion (Ref 99).

Naphthenic acid corrosion is usually controlled by simply blending crude oils having high TAN values with other crude oils having lower TAN values. Blending is designed to reduce the naphthenic acid content of the worst side cut. The TAN produced by naphthenic acids in these fractions is usually determined by assessment of TAN as a function of true boiling point for specific fractions in a distillation experiment. However, there are many other variables that can play into a blending strategy, and sometimes, corrosion testing of coupons in samples of the oil or various blends may be required to provide added confidence regarding the blending strategy. For example, the other factors may include one or more of the following:

- The TAN values for the whole crude and critical hydrocarbon fractions
- The specific type of naphthenic acids present (chemical structures) in these fractions
- The total sulfur content

Fig. 15 Naphthenic acid corrosion on top of 150 mm (6 in.) bubble caps made from type 317 (S31700) stainless steel containing 2.95% Mo. Tray temperature was 305 °C (580 °F).

Fig. 16 Variation in organic acid ring structures in naphthenic acids derived from crude oils compared to reagent-grade naphthenic acid. B.P., boiling point. Source: Ref 35

- The specific sulfur speciation of the oil and their presence in the hydrocarbon fractions of interest

In practice, blending often means that the charge to the crude distillation unit has a TAN value of no higher than 0.5 to 1.0. The actual blending can depend on the other variables mentioned previously, which are numerous due to the variability of crude oil compositions available from various new and existing locations around the world. Currently, there are concerns for new sources of crude oil that are characterized as having high TAN but low concentrations of sulfur ($<0.5\%$). The apprehension is that the specific speciation of the organic sulfur could provide conditions where the amount of reactive sulfur is insufficient to minimize naphthenic acid attack in some portion of the distillation process.

For cases where resistance to naphthenic acid corrosion is based on unit upgrading to corrosion-resistant alloys, vacuum tower internals operating in the 290 to 345 °C (550 to 650 °F) range should be made from type 316

(S31600) or, preferably, type 317 (S31700) stainless steel containing a higher molybdenum content (3.5%). This is often a good strategy, because in many cases, the vacuum gas oils contain the highest concentrations of naphthenic acids and have the lowest TAN values. The vacuum tower lining in this temperature range should also be type 317 (S31700) stainless steel. Aluminum has excellent resistance to naphthenic acid corrosion in vacuum towers and can be used if its strength limitations and low resistance to velocity effects are kept in mind. Alloy 20 (N08020), alloy C-276 (N10276), alloy 625 (N06625), and Ti-grade 2 (R50400) are also resistant to naphthenic acid corrosion, if needed for specialty equipment. In contrast, aluminized carbon steel tray components, such as bubble caps, have performed poorly.

Fuel Ash. Corrosion by fuel ash deposits can be one of the most serious operating problems with boiler and preheat furnaces. All fuels except natural gas contain certain inorganic contaminants that leave the furnace with products of combustion. These will deposit on heat-receiving surfaces, such as superheater

tubes, and after melting can cause severe liquid-phase corrosion. Contaminants of this type include various combinations of vanadium, sulfur, and sodium compounds (Ref 132–134). Fuel ash corrosion is very likely to occur when residual fuel oil (Bunker C fuel) is burned.

In particular, vanadium pentoxide vapor (V_2O_5) reacts with sodium sulfate (Na_2SO_4) to form sodium vanadate ($Na_2O \cdot 6V_2O_5$). The latter compound reacts with steel, forming a molten slag that runs off and exposes fresh metal to attack. The cathodic part of the corrosion reaction is reduction of the pentoxide to the tetroxide (V_2O_4); therefore, the most common ingredient of superheater deposits is sodium vanadyl vanadate ($Na_2O \cdot V_2O_4 \cdot 5V_2O_5$). Table 9 lists the ash fusion temperatures of a number of fuel ash ingredients that can contribute to corrosion and fouling in boiler and preheat furnaces.

Corrosion increases sharply with increasing temperature and vanadium content of fuel. If the vanadium content in the fuel oil exceeds 150 ppm, the maximum tube wall temperature should be limited to 650 °C (1200 °F). Between

20 and 150 ppm V, maximum tube wall temperatures can be between 650 and 845 °C (1200 and 1550 °F), depending on sulfur content and the sodium-vanadium ratio of the fuel oil. With 5 to 20 ppm V, the maximum tube wall temperature can exceed 845 °C (1550 °F).

In general, most alloys are likely to suffer from fuel ash corrosion. However, alloys with high chromium and nickel contents provide the best resistance to this type of attack. Sodium vanadate corrosion can be reduced by firing boilers with low excess air (<1%). This minimizes formation of sulfur trioxide in the firebox and produces high-melting slags containing vanadium tetroxide and trioxide rather than pentoxide. In the temperature range of 400 to 480 °C (750 to 900 °F), boiler tubes are corroded by alkali pyrosulfates such as sodium pyrosulfate and potassium pyrosulfate, when appreciable concentrations of sulfur trioxide are present.

Another problem in fossil fuel combustion units involves the formation of low-melting-point sulfate salts, particularly Na_2SO_4 and potassium sulfate (K_2SO_4). In many boilers that operate at 450 °C (840 °F) and exhibit fireside corrosion in chromium-molybdenum steel com-

ponents, alternative use of Cr-Ni-Mo steels such as type 310 has been generally beneficial. In some cases, these materials are used in the clad form on the outer surface of the boiler tubes, where concerns for high-temperature corrosion are greatest. For higher-temperature service (>650 °C, or 1200 °F), under such conditions as found in superheaters, highly alloyed materials such as cast 50Ni-50Cr alloy have been successfully used for resistance to fireside corrosion. As shown in Fig. 22, maximum corrosive attack is usually found to occur at or around the solidus temperature of the molten salt deposit and the dissociation temperature of low-melting-point eutectics (Ref 135).

The conditions that result from the combustion of low-grade fuel oil are particularly severe and, in many cases, difficult to anticipate, because correlation of corrosion severity to fuel contaminant levels may not have been conclusively determined, or because the process conditions may vary over time. In some applications, it has been possible to monitor this vapor-phase combustion environment, particularly where conditions of salt deposition provide a conductive medium for making electrochemical

measurements. Under these conditions, the use of electrochemical measurements has resulted in an online, real-time method of making adjustments to the combustion environment to minimize the severity of the corrosion. Figure 23 (Ref 136) shows the severity of hot corrosion in a fossil-fueled process unit versus time, using these methods. Usually, an array of sensors is used to measure the spatial distribution of the corrosion with respect to burners. Additionally, the temperature of the surface of the probe can be internally cooled and controlled to assess the corrosivity relating to various temperatures at different locations in the unit.

In some cases, where alloys are not effective in reducing corrosion or where changes in fuel contaminants are anticipated, additives such as magnesium hydroxides $\text{Mg}(\text{OH})_2$, in the combustors can be used to thermodynamically modify the combustion environment, which can change associated deposits and their resulting morphology. These additives can be helpful in controlling corrosion, particularly in conjunction with controlled firing with low excess air. The additives effectively raise the solidus temperature of salt deposits to a point above the service temperature, allowing more-economical commercial alloys to be used. A porous and fluffy deposit layer is usually formed with the use of these additives. This type of deposit can be readily removed by periodic cleaning. Magnesium-type additives offer additional benefits with regard to cold-end corrosion in boilers. However, the effectiveness of the additives varies. Under some conditions, sulfuric acid vapors can also condense at temperatures between 150 and 175 °C (300 and 350 °F),

Fig. 21 Influence of H_2S on inhibition of naphthenic acid corrosion of a 9Cr-1Mo steel as a result of addition of H_2S gas, or H_2S formation in off-gas in oil containing 1,9-nonanedithiol (NET) or dibenzothiophene (DBT). Amount of H_2S measured in the test off-gas in each case is shown on bottom axis.

Table 9 Ash fusion temperatures of slag-forming compounds

Chemical compound	Chemical formula	Ash fusion temperature	
		°C	°F
Vanadium pentoxide	V_2O_5	690	1270
Sodium sulfate	Na_2SO_4	890	1630
Nickel sulfate	NiSO_4	840	1545
Sodium metavanadate	$\text{Na}_2\text{O} \cdot \text{V}_2\text{O}_5$	630	1165
Sodium pyrovanadate	$2\text{Na}_2\text{O} \cdot \text{V}_2\text{O}_5$	655	1210
Sodium orthovanadate	$3\text{Na}_2\text{O} \cdot \text{V}_2\text{O}_5$	865	1590
Nickel orthovanadate	$3\text{NiO} \cdot \text{V}_2\text{O}_5$	900	1650
Sodium vanadyl vanadate	$\text{Na}_2\text{O} \cdot \text{V}_2\text{O}_4 \cdot 5\text{V}_2\text{O}_5$	625	1155
Sodium iron trisulfate	$2\text{Na}_3\text{Fe}[\text{SO}_4]_3$	620	1150

Fig. 22 Laboratory-simulated flue gas corrosion versus temperature for selected alloys. Tests were conducted in synthetic flue gas ($80\text{N}_2\text{-}15\text{CO}_2\text{-}4\text{O}_2\text{-}1\text{SO}_2$, saturated with water) with synthetic ash (37.5 mol% Na_2SO_4 , 37.5 mol% K_2SO_4 , 25 mol% Fe_2O_3). Source: Ref 135

depending on sulfur content of the fuel oil, and can cause serious corrosion problems. Additives neutralize free acid by forming magnesium sulfate.

Oxidation. Carbon steels, low-alloy steels, and stainless steels react at elevated temperatures with oxygen in the surrounding air and

become scaled. Nickel alloys can also become oxidized, especially if spalling of scale occurs. The oxidation of copper alloys is usually not a problem, because these are rarely used where operating temperatures exceed 260 °C (500 °F). Alloying with both chromium, nickel, and, to a certain extent, silicon increases oxidation

resistance through promoting the formation of a stable and protective scale on the metal surface (see Fig. 24 and 25 for selected steels and stainless steels in air) (Ref 135). Stainless steels or nickel alloys, with alloy additions of chromium and molybdenum—note exception alloy 400 (N04400)—are required to provide satisfactory oxidation resistance at temperatures above 705 °C (1300 °F). Thermal cycling, applied stresses, moisture, and sulfur-bearing gases will decrease protective scaling and increase rates of corrosive attack. In refineries and petrochemical plants, high-temperature oxidation is primarily limited to the outside surfaces of furnace tubes, tube hangers, and other internal furnace components that are exposed to combustion gases containing excess air.

At elevated temperatures, steam decomposes at metal surfaces to form hydrogen and oxygen and may cause steam oxidation of steel, which is somewhat more severe than air oxidation at the same temperature. Fluctuating steam temperatures tend to increase the rate of oxidation by causing scale to spall and thus expose fresh metal to further attack.

Environmentally Assisted Cracking (SCC, HEC, and Other Mechanisms)

Stress-corrosion cracking (SCC), hydrogen embrittlement cracking (HEC), and other forms of environmentally assisted cracking (EAC) and embrittlement are the most insidious forms of failure that can be experienced by process

Fig. 23 Corrosion rate in a combustion environment versus time as monitored using electrochemical methods is plotted with a key process variable. Fireside corrosion of boiler tubes in coal-fired utilities and waste incineration plants is an expensive and difficult problem to deal with. Special corrosion probes inserted into the firewall are used to directly monitor boiler tube degradation online and in real-time and to optimize the process for maximum efficiency and tube life. equipment, because they tend to strike without warning, with the potential to produce catastrophic results. Usually, there is no noticeable yielding or bulging of the component, there is often no measurable metal loss, and through-thickness cracks can form in as little as hours or minutes in severe cases after exposure to a crack-inducing environment. Susceptibility can often be related to short transients such as process upset, start-up or shutdown conditions, or, in some cases, removal of normally protective corrosion films during surface inspections.

For example, cracking throughout an entire furnace coil occurred within 1 h after exposure to air and the resultant formation of polythionic acids. Towers and heat exchangers have had to be scrapped because of hydrogen blistering, embrittlement, and stress cracking at welds. High-temperature hydrogen attack has resulted in the sudden rupture of pressure vessels. With consequences such as these, the possibility and/or probability of EAC occurring in a given environment should not be underestimated. In most cases, the best path forward is to initially select materials of adequate resistance to the application during the design (or at least during repair or replacement after a failure) phase based on a complete knowledge of the process environment, including start-up and normal operations, including those that occur during hold, upsets, and shutdown. Sometimes, this may require laboratory testing under simulated service conditions to provide additional data on the relative corrosion/cracking susceptibility of various material compositions, heat treatments, and fabricated conditions, or the role of process variables on the cracking process. Normally, coatings and inhibitors are not used to mitigate cracking phenomena unless they are used for only short periods or if no other method is possible.

Stress-Corrosion Cracking

Stress-corrosion cracking phenomena common in the refinery result from exposure to the following service environments:

- Chlorides
- Caustic
- Ammonia
- Amines
- Polythionic acid
- Fuel ethanol

A summary of SCC in these systems is presented in the following sections. More information on the basic mechanisms of SCC can be found in the article "Stress-Corrosion Cracking" in *Corrosion: Fundamentals, Testing, and Protection*, Volume 13A of *ASM Handbook*, 2003. A detailed review of tests for determining susceptibility to SCC can be found in the article "Evaluating Stress-Corrosion Cracking" also in Volume 13A.

Chloride SCC. Chlorides are perhaps the most common cause of SCC of austenitic stain-

less steels and nickel alloys. The literature abounds with studies of the mechanism of cracking, specific environments that accelerate cracking, and tests for predicting cracking tendency. Typically, the higher the applied or residual tensile stresses and the higher the dissolved oxygen concentration, the lower the amount of chloride necessary in an aqueous environment to cause SCC. In some cases, SCC has been identified in environments with as little as 1 ppm chloride under just the right mechanical loading situation (Ref 137). However, in most cases, the permissible limits on chloride ion content in refinery operations are higher.

The usual failure mode of chloride SCC in austenitic stainless steels is the transgranular, highly branched cracking illustrated in Fig. 26. Intergranular cracking is sometimes also associated with chloride SCC, but this is not common unless the material is sensitized during welding, heat treatment, or from prolonged exposure to elevated process temperatures.

Based on laboratory tests in boiling 42% magnesium chloride solution, austenitic stainless steel and nickel alloys are subject to chloride SCC if their nickel content is less than approximately 45% (Fig. 1). In practice, however, stainless steel and nickel alloys containing greater than 30% Ni will be immune to chloride SCC in most refinery environments. It has also been reported that chloride SCC can be associated with anaerobic conditions where chlorides are present with high concentrations of H_2S (Ref 138).

Fig. 26 Chloride stress-corrosion cracking of type 304 (S30400) stainless steel tube by chloride-containing sour water. 70×

In some particular cases involving high temperature ($>150\text{ }^{\circ}\text{C}$, or $300\text{ }^{\circ}\text{F}$) and high chloride concentration ($>10,000\text{ ppm}$), austenitic stainless steels and alloys with an excess of 42% Ni can fail by SCC when the service environment involves high partial pressures of H_2S . Material conditions that promote this behavior are high strength resulting from heat treatment and/or cold working, or the presence of elemental sulfur in the service environment.

Factors that normally influence the rate and severity of chloride SCC in refinery environments are chloride content, oxygen content, temperature, stress level, and pH value of an aqueous solution. In most cases, refinery process environments have low chloride concentrations ($<1000\text{ ppm}$). It has been established that, in the absence of H_2S , oxygen is usually required for chloride cracking to occur. Refinery and petrochemical plant experience confirms that stainless steel components, such as heat-exchanger tube bundles, usually do not crack until removed from operation and exposed to air during a shutdown. Increased oxygen content decreases the critical chloride content for cracking to occur, as shown in Fig. 27 (Ref 139).

The severity of cracking also increases with temperature. Cracking of austenitic stainless steel components rarely occurs at ambient temperatures unless extremely severe environmental conditions, grain-boundary sensitization, and high residual tensile stresses occur. Stainless steel pump impellers in seawater service have shown no cracking problems despite the fact that both chloride and oxygen contents are high. Cracking has been found to occur, however, at tropical locations where direct exposure to the sun can increase metal temperatures significantly above ambient. As a general rule, chloride SCC of process equipment occurs only at temperatures above approximately $60\text{ }^{\circ}\text{C}$ ($140\text{ }^{\circ}\text{F}$).

Fig. 27 Synergistic effect of chlorides and oxygen on the stress-corrosion cracking (SCC) of type 304 (S30400) stainless steel. The tests were conducted at $250\text{ to }300\text{ }^{\circ}\text{C}$ ($480\text{ to }570\text{ }^{\circ}\text{F}$) at a strain rate of $<10^{-5}\text{ s}^{-1}$. Source: Ref 139

The stresses required to produce cracking can be assumed to be always present. Residual stresses from forming, bending, or joining operations are sufficient for cracks to form. Thermal stress-relief treatments at 870 °C (1600 °F) can effectively prevent cracking if done correctly and without the necessity of subsequent cold working (to correct distortion, for example). However, prolonged heating in the range of 650 to 815 °C (1200 to 1500 °F) can result in sensitization, depending on the carbon content of the material, which will increase susceptibility to intergranular SCC.

In alkaline solutions, the likelihood of chloride SCC is greatly reduced. Consequently, austenitic stainless steels are frequently used for equipment exposed to amine solutions in gas-treating, sour water, and sulfur recovery units. A survey of plant experiences has shown no reported instances of cracking despite the fact that chloride contents as high as 1000 ppm were measured in the circulating amine solution.

Most cracking problems occur when unexpected chlorine concentrations are found in process streams or in the atmospheric environment. For example, chloride SCC resulted from exposure to seawater spray carried by prevailing winds at a plant at a near-coastal location. The spray soaked the insulation over type 304 stainless steel. The chlorides were then concentrated by evaporation, and cracking occurred at areas of high residual tensile stresses around welds. Other frequent causes of chloride SCC are water dripping on warm stainless piping, thereby concentrating chlorides by evaporation, and water leaching chlorides from thermal insulation (a related problem to corrosion under insulation).

As discussed previously, chlorides are present in a number of refining units, including crude distillation, hydrocracking, hydrotreating, and reforming. However, the amounts are usually low when compared to upstream oil and gas operations. High levels of chlorides are more often found in other units as contamination from upstream processing, or they are introduced with stripping steam, process water, or cooling water. The latter is a particular problem in petrochemical processes that use stainless steel heat exchangers to make steam as a means of recovering waste heat. Any chloride contamination of boiler feed water can result in chlorides concentrating on heat-exchanger tubes and can cause pitting and SCC. As a rule, austenitic stainless steels are not recommended for components in which water is likely to evaporate or condense out.

When superior resistance to chloride SCC in aqueous sulfide-containing media is required, ferritic stainless steel or duplex stainless steels can be substituted for austenitic stainless steels (Ref 139–141). The ferritic or duplex austenitic/ferritic microstructure in these materials provides added resistance to chloride SCC as long as proper microstructural and chemical control is provided in procurement and weld fabrication of these materials. Ferritic stainless steels, such

as type 405 (S40500) or type 430 (S43000), are not susceptible to chloride SCC, but susceptibility to hydrogen embrittlement can occur. As mentioned previously, the duplex stainless steels have a mixed ferritic-austenitic structure and are more resistant to chloride SCC but are not immune to highly aggressive environments with high chloride concentrations and/or low pH (pH < 4.0).

For example, cold-worked type 329 (S32900) duplex stainless steel has cracked when chlorides were concentrated by vaporization of a process stream, as shown in Fig. 28. Some of the new proprietary duplex stainless steels, such as 3RE60 (S31500), 2205 (S31803), and 2507 (S32750), have shown increased resistance toward chloride SCC. However, even these materials have limitations, and highly alloyed austenitic stainless steels, such as AL6XN (N08367), 904L (N08904), alloy 28 (N08028), or nickel-base alloys, must be considered. Generally, resistance to chloride SCC increases with resistance to pitting attack based on the pitting resistance equivalent number (PREN) discussed earlier in this article (see Eq 1).

There are no simple methods (e.g., inhibitors or coatings) of preventing SCC when an austenitic stainless steel is used in an environment known to contain chlorides. For example, in some marginal cases, plating of electroless nickel on conventional austenitic stainless steel has resulted in a decrease in SCC susceptibility due to the cathodic protection provided by the nickel layer. However, this is usually temporary, as a result of the sacrificial nature of the nickel alloy coating, in this case.

Chloride SCC in refineries and petrochemical plants often occurs under shutdown conditions when air and moisture enters equipment opened for inspection and repair. It has been found that the precautionary measures outlined in NACE RP0170 for the prevention of cracking by polythionic acids also help prevent cracking by chlorides in the absence of polythionic acid formation (Ref 142). In particular, excluding air and moisture by nitrogen blanketing and rinsing equipment with an aqueous 0.5% sodium nitrate solution have been shown to inhibit chloride SCC temporarily. To prevent chloride SCC on the outside of insulated pipe, aluminum foil has been wrapped between the insulation and pipe to provide some measure of cathodic protection. One method of preventing the catastrophic failure of components by chloride SCC is the use of austenitic stainless steel as an internal cladding. Carbon or low-alloy steel base metal used as an outer layer would not be susceptible to cracking in chloride solutions, but some localized corrosion may occur. This type of construction also provides resistance to cracking when chlorides are liable to contact the outside of the components, as in external insulation, for example.

Caustic Cracking. The SCC of various steels and stainless steels by caustic (sodium hydroxide, NaOH) is also fairly common in refinery and petrochemical plant operations. Caustic is

added in the form of 5 to 40% aqueous solution to certain process streams in order to neutralize residual acid catalysts, such as sulfuric acid, hydrofluoric acid, and hydrochloric acid. Caustic is also added to cooling water and boiler feed water to counteract large decreases in pH value due to process leaks.

Although caustic attack is primarily in the form of localized corrosion (gouging) in some process streams (for example, crude oil), in others it may take the form of SCC. Traces of caustic can become concentrated in boiler feed water and cause SCC (caustic embrittlement). This occurs in boiler tubes that alternate between wet and dry conditions (steam blanketing) often resulting from overfiring or the development of local hot spots on tubes. Locations such as cracked welds or leaky tube rolls can form steam pockets with cyclic overheating and quenching conditions. These frequently lead to caustic embrittlement, because overheating and evaporation can leave caustic to concentrate in the remaining liquid. The caustic soda service chart discussed previously in this article (Fig. 3) should be consulted for guidance regarding selection of materials and the necessity for stress relief to resist corrosion and SCC in caustic environments. It is based on the operating temperature and anticipated caustic concentration that defines the materials of construction (carbon steel, carbon steel with stress relief, and use of nickel alloys).

Caustic SCC of carbon steel generally occurs at temperatures above approximately 50 to 80 °C (120 to 180 °F), depending on caustic concentration, with the temperature decreasing

Fig. 28 Chloride stress-corrosion cracking of type 329 (S32900) stainless steel by chloride salts that concentrated as water evaporated

with increasing caustic concentration. Welded carbon steel components that are exposed to caustic solutions above these temperatures should be postweld heat treated at 620 °C (1150 °F) for 1 h per 25 mm (1 in.) of metal thickness. However, lines that are under service conditions less than 50 °C (120 °F) that may experience steam cleaning, steam tracing, or hot ambient temperatures during shutdown should also be stress relieved. Caustic SCC of austenitic stainless steels generally occurs between 105 and 205 °C (220 and 400 °F), depending on caustic concentration.

Caustic cracking of austenitic stainless steels is often difficult to distinguish from cracking by chlorides, particularly because common grades of caustic also contain some sodium chloride. As a general rule, however, SCC by chlorides in nonsensitized material is usually, but not always, in the form of highly branched, transgranular cracking, while caustic causes intergranular SCC. However, it can sometimes result in transgranular cracking, particularly if chlorides are present in the caustic environment.

Caustic SCC of carbon steel is often initiated at discontinuities in areas of surface deformation as a result of cold working or welding operations (Ref 143). Although caustic SCC occurs over a wide range of temperatures, there appears to be no correlation between temperature and time-to-failure. Because few failures have been reported at near-ambient temperatures, it appears that crack initiation times are inordinately long unless defects (such as weld defects) are involved. Dynamic strains (either imposed during testing or as a result of variable mechanical loading and thermal stresses in actual components) can also accelerate caustic SCC.

Caustic cracking of carbon steel has been found to occur over a narrow range of potentials near the active current peak of potential/log current curves. Typically, this potential range is centered at approximately -700 mV versus the standard hydrogen electrode. The most negative (active) potential for inducing caustic cracking coincides with the potential for initiating passivation by magnetite (Fe_3O_4) formation. Cracking is promoted by small amounts of dissolved oxygen, sodium chloride, lead oxide, silica, silicates, sulfates, nitrates, permanganate, and chromates that cause the active corrosion potential to move slightly in the positive (noble) direction. In contrast, large amounts of these substances act as inhibitors by pushing the corrosion potential into the passivation range. Phosphates, acetates, carbonates, and tannins also act as inhibitors.

Other caustic salts can be present in refining and petrochemical operations, such as those involving exposure to syngas, and can also cause SCC. For example, the fracture of a stainless steel pipe in a hydrogen-manufacturing facility resulted in an investigation of SCC of 304L stainless steel and 1.25Cr-1.5Mo low-alloy steel in aqueous potassium hydroxide solutions. Both alloys were found to crack in this environment. The low-alloy steel cracked at lower

temperatures than did the stainless steel. Further, it was determined that the cracking of stainless steel was aggravated by the reducing environment in the process resulting from the presence of hydrogen or carbon monoxide. However, the presence of carbon dioxide in contact with potassium hydroxide solutions tends to neutralize them and reduce the susceptibility to cracking. In general, SCC in the potassium hydroxide environment required higher temperatures to crack the stainless alloy than was generally noted for aqueous sodium hydroxide environments. An upper service temperature limit of between 216 and 299 °C (421 and 570 °F) was found for the low-alloy steel (Ref 144).

Ammonia Cracking. Ammonia has caused two types of SCC in refineries and petrochemical plants. The first is cracking of carbon steel in anhydrous ammonia service, and the second type is cracking of copper alloys, such as admiralty metal (C44300). In copper alloys, SCC can occur by ammonia contamination of process streams or by ammonia-based neutralizers that are added to control corrosion. There have even been cases of ammonia-based fertilizers used on adjacent property combining with atmospheric moisture and ammonia compounds in leak-detection fluids that have resulted in SCC of copper alloy refinery equipment.

Carbon steel storage vessels, primarily spheres, have developed transgranular SCC in anhydrous ammonia service at ambient temperature but elevated pressure. In most cases, cracking was detected by inspection before leakage or rupture, but there were at least two catastrophic failures (Ref 145). There have been few problems with semirefrigerated storage vessels and no documented cases of SCC in cryogenic storage vessels. The primary causes of cracking are high stresses, hard welds, and even minor air contamination. Levels of oxygen greater than 5 to 10 ppm can sustain SCC, and this value goes down to only 1 ppm when combined with carbon dioxide. However, the presence of more than 0.1% water tends to reduce SCC susceptibility.

To minimize the likelihood of cracking, only low-strength steels, with a maximum tensile strength of 483 MPa (70 ksi), should be used in anhydrous ammonia service. Welds should be postweld heat treated at 595 °C (1100 °F) or higher, with a maximum allowable hardness of 225 HB. A water content of at least 0.2% should be maintained in the ammonia to effectively inhibit cracking. Air contamination increases the tendency toward cracking and should be minimized, if necessary, by the addition of hydrazine to the water. With a water content of 10 ppm, the oxygen content should be below 10 ppm for safe operation (Ref 146). The permissible oxygen content increases to 100 ppm with a water content of 0.1%. Regular inspection of all components in anhydrous ammonia service is recommended.

Cracking of admiralty metal (C44300) heat-exchanger tubes has been a recurring problem in a number of refining units and petrochemical

process units. For example, ammonia is often used to neutralize acidic constituents, such as hydrogen chloride or sulfur dioxide, in overhead systems of crude distillation or alkylation units, respectively. Stripped sour water containing residual ammonia is used as desalter water at some crude distillation units. This practice causes ammonia contamination of the overhead system even if no ammonia is added intentionally. Ammonia is formed from nitrogen-containing feed stocks during catalytic cracking, hydrotreating, and hydrocracking operations. As a rule, cracking of admiralty metal (C44300) tubes occurs only during shutdowns, when ammonia-containing deposits on the tube surfaces become exposed to air. To prevent cracking, tube bundles should be sprayed with a very dilute solution of sulfuric acid immediately after they are pulled from their shells in order to neutralize any residual ammonia. Cracking of admiralty metal (C44300) tubes has occasionally been attributed to traces of ammonia in cooling water.

Amine Cracking. Stress-corrosion cracking of carbon steel by aqueous amine solutions, which are used to remove H_2S and carbon dioxide from refinery and petrochemical plant streams, has been a recurring problem. In one case involving a 20 wt% monoethanolamine solution, the affected equipment included two amine storage tanks, four absorber towers, a rich-amine flash drum, a lean-amine treater, and various piping (Ref 147). Cracking was found primarily at welds exposed to amine solutions at temperatures ranging from 50 to below 95 °C (125 to 200 °F). Cracking was intergranular, with crack surfaces covered by a thin film of magnetite. These oxide-filled cracks sometimes make inspection by dye-penetrant and magnetic-particle techniques difficult.

No cracking was found in piping that had received postweld heat treatment and was operating at temperatures as high as 155 °C (310 °F). Consequently, most of the affected components were replaced with new ones that had received postweld heat treatment. After careful magnetic-particle inspection, the rest of the components were repaired with welds receiving postweld heat treatment in situ or, where stress relieving was not possible, shot peening, or last-pass heat sink welding was used to provide residual compressive stresses to exposed surfaces around the welds. This compressive layer is a preventative measure but will not remain so if penetrated by corrosion or local pitting. The use of these techniques may be governed or limited by various codes and standards. For example, API RP 945 provides guidance on fabrication and inspection techniques to minimize the occurrence of amine SCC (Ref 148).

In another case, a number of leaks were discovered at piping welds in lean-amine service at temperatures between 40 and 60 °C (100 and 140 °F). None of these welds had been postweld heat treated. Again, the affected components were replaced with new ones that had received a postweld heat treatment (Ref 149).

Cracking of piping welds has also occurred in lean-amine piping of several gas-treating plants, but in all cases, temperatures were well above 95 °C (200 °F). For various reasons, these welds had not been postweld heat treated. Different types of amine solutions, including monoethanolamine, diethanolamine, and sulfinol (containing diisopropanolamine), have been involved in SCC; this confirms that cracking is not limited to monoethanolamine solutions.

Amine SCC appears to be a form of alkaline SCC that is similar in many ways to caustic SCC. The failure mode is intergranular cracking in otherwise ductile material, usually without the formation of substantial corrosion products. Actually, in amine systems, SCC appears related to conditions of marginal passivity and especially to a limited range of conditions around the transition from passive to local active behavior. Responsible species include sulfide, carbon dioxide, chloride, and cyanide. In amine solvents, carbonate films tend to passivate steel, while the presence of low levels of sulfide, thiosulfate, and thiocyanate can destabilize these normally protective films, leading to local anodic sites that initiate into SCC. Table 10 shows the influence of amine concentration, temperature, and the influence of impurities on susceptibility to the formation of fissures in slow

strain-rate test specimens resulting from amine SCC (Ref 150).

Cracks, which typically run parallel to the weld, are found in the weld metal, in the base metal (~5 mm, or 0.2 in., away from the weld), and in the HAZ. Cracking is not related to weld hardness. To prevent amine SCC, postweld heat treatment at 620 °C (1150 °F) was recommended in the past for carbon steel welds exposed to amine solutions at temperatures exceeding 95 °C (200 °F). In light of the recently reported failures, welds of carbon steel components in amine service should be postweld heat treated regardless of service temperature.

Polythionic Acid Cracking. Stress-corrosion cracking of austenitic stainless steels by polythionic acids was first identified with the introduction of hydrotreating units. Austenitic stainless steels were required to provide resistance to high-temperature sulfidic corrosion in the presence of hydrogen. It was found that unstabilized austenitic stainless steel, such as type 304 (S30400), would crack adjacent to weldments during shutdowns. Typically, cracks were found to penetrate piping with a wall thickness of 12 mm (0.5 in.) in less than 8 h. Failures have been limited mostly to furnace tubes, heat-exchanger tubes, thermowells, and vessel linings (Ref 151). Similar cracking was

also found in hydrocracking units and, more recently, in catalytic cracking units, in which austenitic stainless steels have found greater use because of an increase in catalyst regeneration temperatures (Ref 152).

Examples of SCC by polythionic acids are shown in Fig. 29 through 31. The cracking in roll-bonded cladding of type 304 (S30400) stainless steel (Fig. 29) is similar to mud cracking. Figure 30 shows the cracking that occurred in a type 304 (S30400) furnace tube near the weld to a carbon steel tube. These cracks are both parallel and perpendicular to the weld, reflecting different stresses in the weldment. The intergranular mode of crack propagation is shown in Fig. 31 and clearly distinguishes SCC by polythionic acids from chloride SCC (but not from caustic SCC).

Polythionic acid SCC occurs only in austenitic stainless steels and Ni-Cr-Fe alloys that have become sensitized through thermal exposure (Ref 153, 154). Sensitization occurs when the carbon present in the alloy reacts with chromium to produce chromium carbides at the grain boundaries. As a result, the areas adjacent to the grain boundaries become depleted in chromium and are no longer fully resistant to certain corrosive environments.

Sensitization of type 304 (S30400) stainless steels normally occurs at temperatures between 400 and 815 °C (750 and 1500 °F), whenever the alloy is slowly cooled through this temperature range (such as during welding and heat treating), or during normal process operations. The higher the temperature, the shorter the time of exposure required for sensitization.

Table 10 Amine concentration and temperature dependence of cracking in monoethanolamine (MEA) solvents under carbon dioxide atmosphere

MEA concentration, %	Temperature		Characteristics of fissures in slow strain-rate specimens with and without additives in environment		
	°C	°F	No additives	Carbonate/bicarbonate added	Contaminant package added(a)
15	71	160	None	Light	None
	116	240	None	Medium	Slight
25	71	160	Medium	None	Slight
	116	240	Medium	Medium	Severe
50	71	160	None	None	Slight
	116	240	None	None	Slight

(a) Contaminant package included species commonly found in lean-amine stream, including thiosulfate and thiocyanate.

Fig. 30 Polythionic acid stress-corrosion cracking of type 304 (S30400) furnace tube near weld to carbon steel tube. Cracking is both parallel and perpendicular to weld but not in the weld.

Fig. 31 Intergranular cracking typical of polythionic acid stress-corrosion cracking in type 304 (S30400) stainless steel. 75×

Addition of stabilizing elements, such as titanium or niobium, or limiting the amount of carbon are two methods for reducing the effects of welding and heat treating on sensitization. However, they are not effective for long-term exposure to temperatures above 430 °C (800 °F). The resistance of titanium-stabilized type 321 (S32100) stainless steel to polythionic SCC can be significantly improved by a thermal stabilization at approximately 900 °C (1650 °F) and holding for 2 h, with no specific limits on the cooling rate. Thermal stabilization causes the precipitation of carbon as titanium carbide rather than chromium carbide and therefore decreases the amount of carbon available for chromium carbide formation upon subsequent high-temperature exposure. Also, any chromium depletion that does occur near the grain boundaries during this time period will be counteracted by chromium diffusion from within the alloy.

Laboratory studies and plant experiences have demonstrated that austenitic stainless steels are not sensitized when applied as a weld overlay over carbon or low-alloy steels. The lack of sensitization under these conditions was verified by testing stressed samples in a solution containing polythionic acids. As can be seen in Fig. 29, SCC of the roll-bonded cladding stops at the weld overlay around the nozzle.

Polythionic acids of the type $H_2S_xO_y$ (including sulfurous acid) are formed by the reaction of oxygen and water with the iron/chromium sulfide scale that covers the surfaces of austenitic stainless steel components as a result of high-temperature sulfidic corrosion. Because neither oxygen nor water is present during normal operation under conditions in which austenitic stainless steels would be used, SCC evidently occurs during shutdowns. Oxygen and water originate from steam or wash water used to free components of hydrocarbons during shutdown before inspection or simply from atmospheric exposure. In catalytic cracking units, oxygen and water can be present during normal operations at certain locations of the catalyst regeneration system because of steam purges and water sprays for preventing catalyst accumulation. The components involved include air rings, plenums, slide valves, cyclone components, and expansion joint bellows in the catalyst regenerator and associated lines.

In general, however, SCC by polythionic acids is considered to be a problem primarily during shutdown periods; suitable procedures to prevent cracking are outlined in NACE RP0170 (Ref 142). These procedures include nitrogen purging of components that were opened to the atmosphere, purging with dry air having a dewpoint below -15 °C (5 °F), or neutralizing any polythionic acids that are formed, by washing components with a 2% aqueous soda ash (sodium carbonate) solution.

Soda ash solution should also be used for hydrotesting prior to returning components to service. Residues of soda ash solution should be left on components during temporary storage to prevent SCC. The need for this can be

illustrated by an experience with a U-tube heat-exchanger bundle fabricated of type 304 (S30400) stainless steel. After the bundle had been removed from a hydrotreating unit, the external surfaces of the tubes were washed with soda ash solution, which was allowed to dry. Before storing the bundle outdoors, instructions were given to cover it to prevent rainwater from washing off the soda ash residues. It was later discovered, however, that the U-bends had not been covered and that extensive SCC had taken place at these locations.

Stress-Corrosion Cracking in Fuel Ethanol.

The recent results of an experience survey and research program funded by the API and the Renewable Fuels Association indicated that a total of over 20 cases of SCC in carbon steel equipment exposed to fuel ethanol occurred during a period starting in the early 1990s through 2004 (Ref 155). These cases were found in end-user storage and blending facilities (steel tanks, rack piping, and components) and in fuel ethanol distribution storage tanks. No cases of SCC were reported thus far in fuel ethanol manufacturer facilities or tanker trucks, railroad tanker cars, or barges used to transport fuel ethanol. Additionally, no SCC has occurred following blending of fuel ethanol with gasoline. This suggests that SCC may be related to changes in the fuel ethanol as it moves through the distribution chain over a period of days, weeks, or months. From the results of laboratory research studies in simulated fuel ethanol blends, it appears that these likely changes involve aeration (O_2 pickup) during handling, which was found to increase susceptibility to SCC. Furthermore, corrosion monitoring of steel in fuel ethanol environments at two field sites also corroborated the impact of aeration by indicating increased corrosion rate and tendencies for localized corrosion in aerated environments (Ref 155).

Thermodynamic modeling of the fuel ethanol environment in accordance with ASTM D 4806 indicated that during most expected cases, steel equipment should be in a range of active corrosion extending between a passive region (at high potential) and a region of immunity to corrosion (at low potentials). This condition suggests that active-passive behavior could be present, depending on the range of corrosion potentials exhibited during service. Such behavior can be affected by aeration or the presence of oxidizing species in the environment. Furthermore, this also suggests that an active-passive mechanism of SCC in fuel ethanol exists that may be similar to that in other SCC systems involving steel (e.g., carbonate-bicarbonate SCC, CO-CO₂ SCC, etc.). This was consistent with the results of the research conducted by Southwest Research Institute.

While identification of this phenomenon is relatively recent, analysis of field failures has documented that cracking of steel in fuel ethanol is characterized by highly branched, intergranular cracks in highly stressed locations, such as associated with non-postweld heat

treated welds; areas of stress concentration and local bending, such as near lap seam welds; and cyclic loading due to flexing and bending. Techniques used in various situations to reduce the occurrences of SCC in fuel ethanol service include implementation of epoxy coatings to mask welded or highly stressed areas or stress relief when possible. Enhanced guidelines for fuel ethanol service and other techniques to reduce susceptibility to SCC are still being explored.

Wet H_2S Cracking

Corrosion of carbon and low-alloy steels by aqueous H_2S solutions or sour waters (generically referred to as refinery wet H_2S environments) can result in one or more types of environmentally assisted cracking EAC. These forms of EAC are related primarily to the damage caused by hydrogen that results from the production of hydrogen by the sulfide corrosion process in aqueous media. They include loss of ductility on slow application of strain (hydrogen embrittlement), formation and propagation of hydrogen-filled blisters or voids in the material (hydrogen blistering or hydrogen-induced cracking, or HIC), and spontaneous cracking of high-strength or high-hardness steels (hydrogen embrittlement cracking, also known more familiarly as SSC when involving environments that include exposure to H_2S). A monograph of classic papers published on cracking of steels in petroleum upstream and downstream wet H_2S environments was published by NACE International and is given in Ref 156.

In wet H_2S refinery environments, atomic hydrogen (H^0) forms as part of the sulfide corrosion process. When steel corrodes in aqueous H_2S -containing environments, it forms a mostly insoluble FeS corrosion product and also liberates hydrogen atoms (also referred to as monatomic hydrogen). If these hydrogen atoms come in close proximity to each other, they can recombine to form molecular hydrogen (H_2). Once this recombination process takes place on the metal surface, molecular hydrogen is too large to enter the metal lattice. It is only the atomic form of hydrogen that can enter the material during aqueous corrosion and potentially lead to the aforementioned forms of EAC.

During these corrosion processes, hydrogen atoms formed from cathodic reactions first adsorb on the metal surface prior to recombination. It is at this point that the hydrogen atoms can recombine to form H_2 gas that is commonly seen bubbling off the corroding metal surfaces. However, in the presence of certain chemical species known as hydrogen recombination poisons, the formation of hydrogen molecules can be retarded. Sulfur (from H_2S), arsenic, phosphorus, tin, lead, and bismuth are commonly known hydrogen recombination poisons. Due to the retarding effect of sulfur species on the recombination process, the atomic hydrogen produced by the corrosion process is more

likely to reside in the atomic form, become absorbed into the material, and permeate according to its diffusivity and solubility in the microstructure. Information on these processes and ways to measure hydrogen permeation are given in ASTM G 148 (Ref 157).

Sulfide Stress Cracking. While still in the atomic state, monatomic hydrogen can diffuse to and concentrate at sites of microstructural discontinuities such as phase, precipitate or grain boundaries, dislocations, and sites of high stress and/or lattice distortion (strain), where they can interfere with the normal ductility processes of the material. The accumulation of atomic hydrogen in the locally distorted metal lattice is the direct result of the lattice dilation, which is better able to accommodate the presence of the interstitial hydrogen. At sufficiently high concentrations in the solid state, atomic hydrogen can also affect the bonding between atoms to promote decohesion, particularly along grain boundaries and other zones where the lattice has already been distorted by strain, cold working, or hardening. These are solid-state reactions between the atomic hydrogen and the metal lattice and its local defect structures. This is the basis for SSC of steels and most other engineering materials.

Sulfide stress cracking is normally associated with high-strength steels and alloys—yield strength greater than 550 MPa (80 ksi)—and with high-hardness (>22 HRC) structures in weld HAZs. Non-postweld heat treated weldments are particularly problematic, because they often contain both high HAZ hardness and high residual tensile stresses that can initiate SSC and promote crack propagation. Resistance to SSC is usually improved through the use of postweld heat treatment and through the use of lower-carbon-equivalent plate steels and quenched-and-tempered wrought steels.

Hydrogen-Induced Cracking. Once atomic hydrogen has diffused into the material, it can also recombine to form molecular hydrogen (H_2) within the metal at internal defects, inclusions, and pores. Sites for recombination are commonly observed to be weak internal interfaces such

as those at manganese sulfide inclusions or metallurgical laminations. Ferrite-pearlite banding and related inclusions can also produce locally weak interfaces in the material that can result in small hydrogen-filled blisters being produced. Because hydrogen molecules are much larger than atomic hydrogen, once the hydrogen recombines to form hydrogen gas (H_2), it cannot readily diffuse out of these sites. This results in a buildup of pressure inside these blisters, which drives their growth, and eventually results in propagation and linkage of hydrogen-filled blister cracks in the material, commonly known as HIC and also previously referred to as stepwise cracking due to the visual appearance of these cracks stepping through the material (Fig. 32). This phenomenon usually is of concern in lower-strength plate steels—less than 550 MPa (80 ksi) and low hardness (<HRC 22)—used in rolled and longitudinally seam welded or electric resistance welded pipe, or plate steels used in the manufacturing of refinery vessels and tanks.

Stress-Oriented Hydrogen-Induced Cracking (SOHIC). Under conditions of very high hydrogen flux and high tensile stress or high local stress concentration, small blister cracks similar to those normally associated with HIC can become aligned perpendicular to the tensile stress. Often, these cracks align in the through-thickness direction of the material, thereby reducing the load and/or pressure-carrying capabilities of the material and fabricated equipment (Fig. 33). This phenomenon is referred to as SOHIC. This phenomenon has been appreciated as a problem in refinery equipment only within the past 15 years, with the advent of improved lower-sulfur steels. During the 1990s, it was the subject of extensive research by a consortium of companies and by the API to develop a more fundamental understanding of this process and to develop methods for inspection, laboratory testing, and repair of damaged equipment. Further discussion of this and the other hydrogen-cracking mechanisms common in wet H_2S refinery systems are given in several publications (Ref 158–161).

Fig. 32 Hydrogen-induced cracking, which is also referred to as stepwise cracking

Hydrogen-cracking phenomena occur primarily when steel is exposed to aqueous H_2S solutions having low pH values. Under these conditions, corrosion rates are typically high, thus resulting in high hydrogen flux into materials. In the range of pH less than 5, H_2S is chemisorbed to the steel surface and poisons the reaction between hydrogen atoms. Aqueous H_2S solutions having high pH values can also cause severe hydrogen charging and resultant cracking. This normally occurs when cyanides are present in the sour water environment, particularly at slightly elevated temperatures. In the absence of cyanides, aqueous H_2S solutions with pH values above 8 most often do not corrode steel, because a protective iron sulfide film forms on the surface. However, if higher H_2S partial pressures are present, particularly when combined with highly turbulent conditions, corrosion rates increase, as do the resultant hydrogen flux into the material.

Fig. 33 Stress-oriented hydrogen-induced cracking in refinery plate steel. Note the stacked array of hydrogen blister cracks going through the thickness of the material (vertical) oriented perpendicular to the direction of the applied tensile stress (horizontal).

The role of cyanides is to destroy this normally protective sulfide film on the metal surface and convert it into soluble ferrocyanide $[\text{Fe}(\text{CN})_6]^{4-}$ complexes. As a result, the now-unprotected steel can corrode very rapidly with little or no barrier-limiting hydrogen flux. For practical purposes, the corrosion rate depends primarily on the bisulfide ion (HS^-) concentration and, to a lesser extent, on the cyanide ion (CN^-) concentration. The more bisulfide ion that is present, the more cyanide that is required to destroy the protective iron sulfide film. It has been shown experimentally that corrosion of steel in aqueous ammonia/sulfide/cyanide solutions with pH values above 8 is nearly always accompanied by high hydrogen flux and associated cracking or blistering (Ref 162).

Hydrogen Embrittlement. This phenomenon is characterized by decreasing ductility at slow strain rates; this is contrary to the normal ductile behavior of metals in most types of mechanical embrittlement (Ref 163). For example, the ductility of carbon steel has been reported to drop from 42 to 7% when charged with hydrogen (Ref 164). This loss of ductility is observed during slow strain-rate testing (usually in the strain-rate range of 10^{-4} to 10^{-7} s^{-1}) but not during high rate-impact tests, such as the Charpy V-notch test. Failure, in the form of cracking, usually occurs some time after a load is applied to hydrogen-charged steel or during active charging in a sour environment.

Another form of this type of attack occurs when a susceptible material is held at constant load under the influence of hydrogen. When this phenomenon was first discovered in the early 1950s, it was referred to as static fatigue, and the minimum load for failure to occur is known as the static fatigue limit. These terms can be found in some older references, but currently they are usually referred to as delayed failure and threshold stress, respectively, so as not to be confused with mechanical fatigue.

Until initiation of a physical crack in a material, hydrogen embrittlement is usually considered temporary in many materials of construction, such as steel. It can be normally reversed by heating the steel to drive out the hydrogen. The rate of recovery depends on the time and temperature of heating, the amount of hydrogen in the material at the start, and the critical amount of hydrogen to produce embrittlement. For example, high-strength steels have very low critical levels for hydrogen, whereas low-strength materials typically have a much higher tolerance for hydrogen. Heating to 230°C (450°F) and holding for 1 h/25 mm (1 in.) of thickness has been found to be adequate to prevent cracking after welding of constructional steels. Temperatures as high as 650°C (1200°F) for 2 h or as low as 105°C (225°F) for 1 day have also reportedly been used to restore full ductility. There have even been reports that the heat of the sun on a warm summer day was found to be sufficient to restore ductility to a high-carbon, cold-drawn

steel wire that had been embrittled by exposure to a wet H_2S environment. This is the basis for the commonly used method of baking out steels that have been exposed to wet H_2S environments before welding. As a rule, however, heating to temperatures above 315°C (600°F) for any length of time should be avoided to lessen the possibility of high-temperature hydrogen attack during the outgassing process.

Titanium can also become embrittled by absorbed hydrogen as a result of corrosion, excessive cathodic protection, or exposure to hydrogen gas (Ref 25). When hydrogen is absorbed by titanium in excess of approximately 150 ppm, a brittle titanium hydride phase will form, as shown in Fig. 34. Embrittlement due to titanium hydride precipitation is usually permanent and can be reversed only by vacuum annealing, which is difficult to perform. Absorption of hydrogen by titanium dramatically increases once the protective oxide film normally present on the metal is damaged through either mechanical abrasion or chemical reduction. Hydrogen intake is accelerated by the presence of surface contaminants, including iron smears, and occurs predominantly as temperatures exceed 70°C (160°F).

Hydriding can be minimized by anodizing or thermal oxidizing treatments to increase the thickness and resistance of the normally protective titanium oxide film. If it is impractical to apply these treatments, acid pickling of titanium components—with 10 to 30 vol% nitric acid containing 1 to 3 vol% hydrofluoric acid at 49 to 52°C (120 to 125°F) for 1 to 5 min—can be performed to remove iron smears. Acid pickling is also recommended for cleaning titanium components after inspection and repairs during shutdowns, especially components exposed to concentrated acetic acid in certain petrochemical operations. To minimize hydrogen pickup during pickling, the volume ratio of nitric acid to hydrofluoric acid should be near 10. In some highly aggressive process environments, titanium components may have to be electrically insulated from more anodic components, such as aluminum, to prevent hydride formation as a result of hydrogen evolution on titanium surfaces from the resultant cathodic polarization. A similar situation is found when titanium is used in systems involving other metals under cathodic protection with impressed current or sacrificial anodes (zinc, aluminum, or magnesium). This level of cathodic polarization can also induce hydride formation. It may be necessary to limit cathodic polarization or totally isolate the titanium from the other materials. When process streams contain a significant volume of hydrogen (for example, reactor effluent from hydrotreating units), titanium should be used only at temperatures below 175°C (350°F).

Information on the mechanisms of hydrogen embrittlement is available in the article “Hydrogen Damage” in *Corrosion: Fundamentals, Testing, and Protection*, Volume 13A of *ASM Handbook*, 2003. Test procedures are

reviewed in the article “Evaluating Hydrogen Embrittlement,” also in Volume 13A.

Experience with Hydrogen Blistering, HIC, and SOHIC. These phenomena have been a problem primarily in the vapor recovery (light ends) section of catalytic cracking units and, to a lesser degree, in the low-temperature areas of the reactor effluent section of hydrotreating and hydrocracking units (Ref 165–167). Hydrogen blistering has also been seen in the overhead systems for sour water stripper towers and amine regenerator (stripper) towers, as well as in the bottom of amine contactor (absorber) towers.

An example of hydrogen blistering in an absorber/stripper tower of a catalytic cracking unit is shown in Fig. 35. Hydrogen blistering often accompanies hydrogen embrittlement as a result of aqueous sulfide corrosion. Internal hydrogen blistering on a microscopic scale can lead to HIC. Cracking proceeds in the metal ligaments between adjacent blister cracks because of the resultant tensile stresses produced ahead of the propagating hydrogen blister crack. As a rule, the severity of hydrogen blistering depends on the severity of corrosion and the efficiency of hydrogen charging, which depends heavily on the chemical nature of the environment (H_2S partial pressure, pH, temperature, presence of cyanides). In some cases, some alkaline sour water environments that produce low corrosion rates have high enough charging efficiencies to produce high hydrogen fluxes and consequently cause extensive damage (Ref 161).

In older vintage and low-quality steels, hydrogen blistering is associated with dirty steel (i.e., high sulfur) with highly oriented slag

Fig. 34 Hydride formation in Ti-grade 2 (R50400) after galvanic coupling to carbon steel in sour water at 110°C (230°F)

inclusions or laminations. These materials have produced large internal blisters in plate steels used to construct pressure vessels and tanks. In some cases, these blisters can reach a size of 30 cm (1 ft) diameter or greater. More modern steels used in refinery operations with low to intermediate sulfur levels typically can show susceptibility to HIC. This can produce smaller blister cracks, but they can link up to produce steplike cracks through the wall of the steels. In these cases, low sulfur concentrations (<0.004 wt%) and/or alloying additions of calcium are used in combination to increase HIC resistance of steels. Lowering the sulfur content increases the cracking resistance due to the reduction in the size and number of sulfide inclusions. Calcium additions provide sulfide shape control, thus resulting in more spheroidal-shaped inclusions, which are less likely to initiate and propagate HIC.

It was also found that some steels with advanced processing and low sulfur composition and low susceptibility to HIC, as found by the standard NACE TM0284 HIC test method (Ref 168), exhibited high susceptibility to SOHIC when under service conditions involving high hydrogen flux and high tensile stress (this experience is usually associated with welded equipment under refinery sour water conditions involving the presence of cyanide in the process environment). This susceptibility was found to relate to microstructural and other factors. Plate materials with highly banded microstructures had low threshold stresses and failed by SOHIC in wet H_2S tests per NACE TM0103 (Ref 169) and also had low susceptibility to crack propagation in the presence of stress concentrators (weld defects, SSC, notches,

machined slots) in full-scale vessel tests under internal pressure and sour solutions. It was also shown that the presence of fine precipitates from overtreatment with calcium in ultralow-sulfur plate steels also influenced susceptibility (Ref 170).

Vapor/liquid interface areas in equipment also show higher damage rates. It is presumed that this is because ammonia, H_2S , and cyanides concentrate in the thin water films or in water droplets that collect at these areas. Local turbulence and flashing can also disrupt normally protective sulfide films on the metal surface at these locations.

The basic approach toward reducing corrosion and hydrogen blistering in the various vapor-compression stages of catalytic cracking units should be aimed at decreasing the concentration of cyanide and bisulfide ions in water condensate. Several methods for accomplishing this have been tried over the years (Ref 171, 172), including conversion of cyanide to generally harmless thiocyanate (SCN^-) by injection of air or ammonium polysulfide solutions at various locations. While this has beneficial effects, it has often produced undesirable side effects, such as accelerated corrosion and fouling at stagnant or low-flow areas. In contrast, reducing the concentration of the sour water and its impurities by injection of wash water in the compressed wet gas streams, in conjunction with corrosion inhibitor injection, has been found to be very effective when applied correctly and consistently (Ref 173). Water washing reduces the concentration of cyanides by improved contacting of vapors and dilution of water condensate. To prevent dissolved and suspended solids from fouling the compressor aftercooler,

only water of fairly good quality, such as boiler feed water or steam condensate, should be injected. To reduce the amount of fresh water used, stripping-steam condensate from the reflux drum can be used. As a rule, there is sufficient stripping-steam condensate to meet the wash-water requirements. This process can be optimized through use of real-time monitoring of corrosion rate and hydrogen permeation to achieve maximum benefit with minimum wash water as the unit feeds and process stream chemistry change (Ref 159).

It is important that the waste sour water from the interstage and high-pressure separator drums be sent directly to waste disposal rather than first being recycled to the reflux drum. Waste water is often recycled for convenience so that its pressure can be reduced in the reflux drum prior to disposal. This alleviates the need for an external depressuring drum but will build up the concentration of ammonia, H_2S , and, especially, hydrogen cyanide in the wet gas leaving the reflux drum. Consequently, excessive concentrations of cyanides will be found in water condensing in the high-pressure stage. Water washing of the overhead of the debutanizer and depropanizer is indicated only if serious fouling problems occur. Normally, these streams are quite dry and should be kept that way to minimize corrosion and hydrogen blistering problems. With proper water washing of the compressed wet-gas stream, water washing of the overhead vapor streams of the debutanizer and depropanizer towers becomes unnecessary.

Corrosion inhibitors help control aqueous sulfide corrosion and hydrogen blistering even though cyanides may still be present. Hydrogen activity probes and chemical tests of water condensate are used to monitor the effectiveness of water washing and inhibitor injection. Where limited hydrogen blistering occurs in certain components of hydrotreating and hydrocracking units, it is usually sufficient to line affected areas with stainless steel or alloy 400 (N04400). This also applies to components of overhead systems for sour water stripper towers and amine regenerator (stripper) towers or the bottoms of amine contactor (absorber) towers.

In recent years, an increase in observations of wet H_2S cracking (HIC, SOHIC, and SSC) was encountered as turnaround inspection frequencies increased after a major failure incident. During this same period, methods for surface inspection improved in sensitivity with the increasing use of wet fluorescent magnetic-particle inspection and ultrasonics. An interesting observation was made that many vessels were found to have occurrences of internal HIC and SOHIC upon multiple inspections. A large-scale vessel test was conducted under the auspices of the API, which identified that removal of the sulfide films on the internal vessel surfaces prior to inspection resulted in a significant increase in hydrogen charging once the vessel was put back into wet H_2S service (Ref 160). This increase in hydrogen flux was then correlated with increasing occurrences of cracking following inspection. Other

Fig. 35 Hydrogen blistering of a carbon steel shell of an absorber/stripper tower in the vapor recovery (light ends) section of a catalytic cracking unit. Note that the blisters have cracked open to the vessel interior.

work showed that application of specific inhibitor compounds that promoted the recombination of atomic hydrogen, while simultaneously allowing the protective sulfide film to reform, substantially reduced postinspection damage of equipment in wet H₂S service (Ref 174).

Guidelines for materials selection for new vessels in refinery wet H₂S service are available in NACE publication 8X194. (Ref 175). Guidelines for inspection and repair of existing vessels are given in NACE RP0296 (Ref 176).

Refinery Experience with SSC. Sour water containing H₂S can cause spontaneous cracking of highly stressed, high-strength steel components, such as bolting and compressor rotors as a result of SSC (Ref 177). Cracking has also occurred in carbon steel components containing hard welds (Ref 178). Cracking can be transgranular, intergranular (with respect to prior-austenite grain boundaries), or mixed mode and will contain sulfide corrosion products, as shown in Fig. 36 and 37. Cracking of this type has become known as SSC and should not be confused with hydrogen-induced (stepwise) cracking presented previously in this article.

Sulfide stress cracking was first identified in the production of sour crude oils when high-strength steels used for well-head and down-hole equipment cracked readily after contacting produced water that contained H₂S. Sulfide stress cracking was not experienced by refineries and petrochemical plants until the introduction of high-pressure processes that required high-strength bolting and other high-strength components in gas compressors. With the increased

use of submerged arc welding for pressure vessel construction, it was found that weld deposits significantly harder and stronger than the base metal could be produced. This led to transverse cracking in weld deposits with hardness greater than 200 HB (Ref 178).

The mechanism of SSC has been the subject of many investigations, most of which attempted to address the cracking seen in high-strength steels instead of the lower-strength steels used in refinery and petrochemical plant equipment. In general terms, SSC occurs in the same corrosive environments that lead to the other forms of refinery wet H₂S cracking. Hydrogen sulfide affects the corrosion rate and the relative amount of hydrogen absorption but otherwise does not appear to be directly involved in the cracking mechanism. As a general rule of thumb, SSC can be expected to occur in process streams containing in excess of 50 ppm H₂S in the gas phase (not dissolved in solution). However, SSC susceptibility is actually related to the partial pressure of H₂S in the service environment, and this H₂S limit may vary with total pressure. Therefore, there can be SSC occurring at lower H₂S concentrations.

There is also a direct relationship between H₂S concentration and the allowable maximum hardness value of the HAZ on one hand and cracking threshold stress on the other. Typically, the allowable maximum hardness value decreases 30 HB, and the allowable threshold stress decreases by 50% for a tenfold increase in H₂S concentration (Ref 179). Also, SSC occurs most readily at or near ambient temperature, with

susceptibility decreasing with increasing service temperature. As in the case of hydrogen embrittlement and hydrogen blistering, SSC of steel in refineries and petrochemical plants often requires the presence of cyanides.

The most effective way of preventing SSC is to ensure that the steel is in the proper metallurgical condition. This usually means that weld hardness is limited to 200 HB (Ref 180). Because hard zones can also form in the HAZs of welds and shell plates from hot forming, the same hardness limitation should be applied in these areas. Guidelines for dealing with the SSC that occurs in refineries and petrochemical plants are given in API RP 942 (Ref 181) and NACE RP0472 (Ref 182). The most comprehensive guidelines for materials selection for resistance to SSC in refinery operations are now provided in NACE MR0103 (Ref 183).

Postweld heat treatment of fabricated equipment will greatly reduce the occurrence of SSC. The effect is twofold: First, there is the tempering effect of heating to 620 °C (1150 °F) on most hard microstructures (the possible exception being highly microalloyed steels), and second, the residual stresses from welding or forming are reduced. The residual tensile stresses typically represent a much larger effect on the equipment than the internal pressure or other mechanical stresses.

A large number of the ferrous alloys, including stainless steels, as well as certain nonferrous alloys, are susceptible to SSC. Cracking may be expected to occur with carbon and low-alloy steels when the tensile strength exceeds 550 MPa (80 ksi). Because there is a relationship between hardness and strength in steels, the aforementioned strength level approximates the 200 HB hardness limit. For ferrous and nonferrous alloys used primarily in upstream oil field equipment, limits on hardness and/or heat treatment have been established in NACE MR0175/ISO 15156 (Ref 184). In the past, versions of this standard have also been used for petroleum refinery service. However, due to their acidic nature and high levels of chloride, many oil field environments can be generally more corrosive than those encountered during many refining operations (the exception being refinery environments with cyanide). It is now recommended that the MR0175 standard not be used for selection of materials for petroleum refining service. The use of the newer NACE MR0103 standard for refinery operations is preferred (Ref 183).

Hydrogen Attack

The term *hydrogen attack* (or, more specifically, high-temperature hydrogen attack) refers to the deterioration of the mechanical properties of steels in the presence of hydrogen gas at elevated temperatures and pressures. Hydrogen attack is potentially a very serious problem with regard to the design and operation of refinery equipment in hydrogen service (Ref 185, 186).

Fig. 36 Sulfide stress cracking of a hard weld of a carbon steel vessel in sour water service. BHN, Brinell hardness. 40×

Fig. 37 Sulfide stress cracking of hard heat-affected zone next to weld in A516-70 pressure vessel steel after exposure to sour water. 35×

It is of particular concern in hydrotreating, reforming, and hydrocracking units at above roughly 260 °C (500 °F) and hydrogen partial pressures above 689 kPa (100 psia) (Ref 187). Under these conditions, molecular hydrogen (H_2) dissociates at the steel surface to atomic hydrogen (H^0), which readily diffuses into the steel. At grain boundaries, dislocations, inclusions, gross discontinuities, laminations, and other internal voids, atomic hydrogen will react with dissolved carbon and with metal carbides to form methane.

The large molecular size of methane actually precludes diffusion and relief of the gas pressure formed inside the material. As a result, internal methane pressures become high enough to blister the steel or to cause intergranular fissuring (Ref 166). At higher temperatures, the dissolved carbon diffuses to the steel surface and combines with atomic hydrogen to evolve methane. Hydrogen attack now takes the form of overall decarburization and loss of material strength.

The overall effect of hydrogen attack is the partial depletion of carbon in pearlite (decarburization) and the formation of fissures (blisters and cracks) inside the metal, as shown in Fig. 38. As attack proceeds, these effects become more pronounced, as shown in Fig. 39, in which partial depletion of carbon is evident in some of the grains, while others are completely decarburized. Hydrogen attack is accompanied by loss of tensile strength and ductility. Consequently, unexpected failure of equipment without prior warning signs (mechanical embrittlement and the associated loss of ductility and toughness) is the primary cause for concern.

Forms of Hydrogen Attack. As briefly mentioned previously, hydrogen attack can take several forms within the metal structure, depending on the severity of the attack, stress, and the presence of inclusions in the steel.

General surface attack occurs when equipment, which is not under high stress, is exposed to hydrogen at elevated temperatures and pressures. As a rule, decarburization is not uniform across the surface or through the thickness; instead, it takes place at various locations

within the structure, such as grain boundaries, carbides, and inclusions. The fissures that form are parallel to the metal surface, often following inclusions, banding, or laminations. The fissures themselves are small and are not linked together, as may happen with more severe stages of attack.

Hydrogen attack also initiates at areas of high stress or stress concentration in the steel, because atomic hydrogen preferentially diffuses to these areas of lattice dilatation. Isolated fingers of decarburized and fissured material are often found adjacent to weldments and are associated with the initial stages of hydrogen attack. It is also evident that the fissures tend to be parallel to the edge of the weld rather than the surface. This orientation of fissures is probably the result of residual stress adjacent to the weldment and/or instability of carbides around the weld HAZ. Fissures in this direction can form into through-thickness cracks.

The necessary stress for inducing localized hydrogen attack is not limited to areas of weldments. Hydrogen attack has been found to be concentrated at the tip of a fatigue crack that initiated at the toe of a fillet weld and propagated along the HAZ of the weld. In this case, the hydrogen-containing process stream evidently entered the fatigue crack and caused fissuring around the crack tip, as shown in Fig. 40. Although no evidence of attack was found in adjacent portions of the piping system, the localized attack was the cause of a major failure.

Severe hydrogen attack can result in blisters and delaminations in steels, as shown in Fig. 41. This is an advanced stage of hydrogen attack, and it is accompanied by complete decarburization throughout the cross section of the steel. The laminar nature of the fissures is typically obtained when no local stresses are present, but the physical appearance of this blistering is quite similar to hydrogen blistering (described earlier in this article).

Prevention of Hydrogen Attack. The only practical way to prevent hydrogen attack is to use steels that, based on plant experience, have been found to be resistant to this type of

deterioration. The following general rules are applicable to hydrogen attack:

- Carbide-forming alloying elements, such as chromium and molybdenum, increase the resistance of steel to hydrogen attack and the progression of related damage.
- Increased carbon content decreases the resistance of steel to hydrogen attack.
- Heat-affected zones are more susceptible to hydrogen attack than the base or weld metal. This is usually associated with differences in their carbide structures and local stresses.

For most refinery and petrochemical plant applications, low-alloy chromium- and molybdenum-containing steels are used to minimize

Fig. 40 High-temperature hydrogen attack, in the form of localized fissuring, at the tip of a fatigue crack that initiated at the toe of a fillet weld. 70×

Fig. 38 High-temperature hydrogen attack of carbon steel in the form of decarburization and fissuring. 50×

Fig. 39 Depletion of carbon in pearlite colonies and formation of grain-boundary fissures due to high-temperature hydrogen attack of carbon steel. 140×

Fig. 41 High-temperature hydrogen attack in the form of blistering and laminar fissuring throughout the wall thickness of a carbon steel pipe

or prevent hydrogen attack. However, questions have been raised regarding the effect of long-term hydrogen exposure on C-0.5Mo steel (Ref 188). As a result, low-alloy steels with higher chromium and molybdenum content are preferred over C-0.5Mo steel for new construction.

The conditions under which different steels can be used in high-temperature hydrogen service are listed in API RP 941 (Ref 189). The principal data are presented in the form of curves referred to as the Nelson curves, as shown in Fig. 42. The curves are based on long-term refinery experience, rather than on laboratory studies. However, recent laboratory data have been used to further understand the time-dependent behavior of hydrogen attack and how it relates to damage observed in service. The curves are periodically revised by the API Subcommittee on Materials Engineering and Inspection, and the latest edition of API RP 941 should be consulted to ensure that the proper steel is selected for the operating conditions encountered. The change in 1990 removed the Nelson curves for C-0.5Mo steels from the body of the API standard. This change was prompted by the documentation of eight cases of hydrogen attack in equipment made from C-0.5Mo steel. The curves for this material are now provided in an appendix for historical purposes only. The selection of C-0.5Mo steels is now based on the curves provided for carbon steels.

Factors that are important for scheduling inspections for high-temperature hydrogen attack of steel equipment in refinery service include:

- Operating conditions (partial pressure of hydrogen and temperature) that are relative to the operating limits provided in API RP 941.
- Metallurgical condition of C-0.5Mo steels in the welded or annealed condition have less resistance to hydrogen attack than these steels in the normalized condition.

- Welds receiving postweld heat treatment are less susceptible to hydrogen attack than in the as-welded condition.

Hydrogen-Induced Disbonding. Another form of damage potentially resulting from refinery high-temperature hydrogen service is hydrogen-induced disbonding (HID) of stainless steel clad or weld overlaid steel plates used in hydroprocessing equipment (Fig. 43). This form of attack usually results in the formation of blisters at or near the bond/fusion line between the steel and stainless alloys. Hydrogen-induced disbonding occurs with increasing frequency at high hydrogen pressures and service temperatures and with increased rapid cooling as a result of process changes and shutdown, start-up cycles (Ref 190). It has also been found that the process of cladding or weld overlaying can also affect susceptibility to HID. A laboratory test procedure involving exposure of bimetallic samples to high-temperature hydrogen environments has been developed and standardized in ASTM G 146 (Ref 191). These procedures can be tailored to specific service applications (temperature, hydrogen partial pressure, and cooling rates) for purposes of qualification of particular fabrication and welding techniques used in vessel construction.

Other Associated Phenomena. In addition to hydrogen attack, hydrogen stress cracking can occur at carbon and low-alloy steel welds that were in hydrogen service above approximately 260 °C (500 °F). Cracking occurs upon cooling and is intergranular and typically follows lines of high, localized stress and/or hardness. Cracking is caused by the increased effect of dissolved hydrogen in the steel at lower temperatures. This phenomenon is prevented by postweld heat treatment. Hydrogen outgassing procedures should be followed when equipment is depressurized and cooled prior to shutdown.

Fig. 42 Operating limits for various steels in high-temperature high-pressure hydrogen service (Nelson curves) to avoid decarburization and fissuring. Source: Ref 189

Stainless steels with chromium contents above 12% and, in particular, the austenitic stainless steels are immune to hydrogen attack. It should be noted, however, that atomic hydrogen will diffuse through these steels; as a result, they will not provide protection against hydrogen attack if applied as a loose lining or an integral cladding over a nonresistant base steel.

Corrosion Fatigue

Corrosion, in conjunction with cyclic stressing, can bring about a significant reduction in the fatigue life of a metal. Failure under these circumstances is described as corrosion fatigue. Rotating equipment, valves, and some piping runs in refineries and petrochemical plants may be subject to corrosion fatigue. In particular, pump shafts and various springs are the two most likely candidates for corrosion fatigue. The types of springs involved include those of scraper-blade devices in a wax production unit, internal springs in relief valves, and compressor valve springs.

Prevention of Corrosion Fatigue. A number of corrective procedures are available for preventing corrosion fatigue. These include increasing the fatigue resistance and/or corrosion resistance of the metal involved, reducing the number of stress cycles or the stress level, and removing or inhibiting the corrosive agent in the environment. Fatigue life can often be increased through heat treatments or alloy changes, which make the metal stronger and tougher. However, this may induce other failure mechanisms such as SSC in the case of wet H₂S environments. Corrosion resistance can be improved by applying protective coatings or by upgrading the material to one of higher alloy content. Design changes can reduce or eliminate vibrations or (in a spring) reduce the stress per cycle. Finally, adding a corrosion inhibitor or removing a source of pitting (i.e., local stress concentrators), such as chlorides, can often increase the corrosion fatigue life. Additional

information on corrosion fatigue is available in the articles "Forms of Mechanically Assisted Degradation" and "Evaluating Corrosion Fatigue" found in *Corrosion: Fundamentals, Testing, and Protection*, Volume 13A of *ASM Handbook*, 2003.

Liquid Metal Embrittlement

Although liquid metal embrittlement has been recognized for at least 60 years, it has received far less attention than the more commonly encountered hydrogen damage or SCC. This is due in part to the fact that the probability of liquid metal contact occurring in refineries and petrochemical plants is normally rather small. In situations in which liquid metal embrittlement has occurred, it has been mainly due to the zinc embrittlement of austenitic stainless steels. Isolated failures have been attributed to welding in the presence of residues of zinc-rich paint or to the heat treating of welded pipe components that carried splatter of zinc-rich paint. However, most of the reported failures due to zinc embrittlement have involved welding or fire exposure of austenitic stainless steel in contact with galvanized steel components.

For example, in one case, severe and extensive cracking in the weld HAZ of process piping made from austenitic stainless steel occurred in a petrochemical plant during the final stages of construction. Much of the piping had become splattered with zinc-rich paint. Although the welders had been instructed to clean piping prior to welding, no cleaning and only limited grinding were performed. After welding, dye-penetrant inspection revealed many thin, branched cracks in the HAZ of welds, as shown in Fig. 44.

In many cases, through-wall cracks cause leaks during hydrotesting. Typically, zinc embrittlement cracks contain zinc-rich precipitates on fracture surfaces and at the very end of the crack tip. Cracking is invariably intergranular in nature (Ref 192).

Several different models for the zinc embrittlement of austenitic stainless steel have been proposed. The most accepted model involves the reduction in atomic bond strength at a surface imperfection, grain boundary, or crack tip by chemisorbed zinc metal. Zinc embrittlement is commonly a relatively slow process that is controlled by the rate of zinc diffusion along austenitic grain boundaries. Zinc combines with nickel, and this results in nickel-depleted zones adjacent to the grain boundaries. The resulting transformation of face-centered cubic austenite (γ) to body-centered cubic ferrite (α) in this region is thought to produce not only a suitable diffusion path for zinc but also the necessary stresses for initiating intergranular cracking. Externally applied stresses accelerate cracking by opening prior cracks to liquid metal.

Although the melting point of zinc is 420 °C (788 °F), no zinc embrittlement has been observed at temperatures below 750 °C (1380 °F),

probably because of phase transformation and/or diffusion limitations. There is no evidence that an upper temperature limit—above which zinc embrittlement does not occur—exists. In the case of zinc-rich paints, only those having metallic zinc powder as a principal component can cause zinc embrittlement of austenitic stainless steels. Paints containing zinc oxide or zinc chromates are known not to cause embrittlement.

Prevention of Zinc Embrittlement. Obviously, the best approach to prevent zinc embrittlement is to avoid or minimize zinc contamination of austenitic stainless steel components in the first place. In practice, this means limiting the use of galvanized structural steel, such as railings, ladders, walkways, or corrugated sheet metal, at locations where molten zinc is likely to drop on stainless steel components if a fire occurs. If zinc-rich paints will be used on structural steel components, shop priming is preferred. Field application of zinc-rich paints should be done after all welding of stainless steel components has been completed and after insulation has been applied. Otherwise, stainless steel components should be temporarily covered with plastic sheathing to prevent deposition of overspray and splatter.

If stainless steel components have become contaminated despite these precautionary measures, proper cleaning procedures must be implemented. Visible paint overspray should be removed by sandblasting, wire brushing, or grinding. These operations should be followed by acid pickling and water rinsing. Acid pickling will remove any traces of zinc that may have been smeared into the stainless steel surface by mechanical cleaning operations. Suitable acid pickling solutions include 5 to 10% nitric acid, phosphoric acid, or weak sulfuric acid. Hydrochloric acid should not be used in order to avoid pitting and intergranular attack of sensitized weldments, or SCC problems. After removal of all traces of acid by water rinsing, final cleaning with a nonchlorinated solvent should be performed immediately before welding. Additional information on liquid metal embrittlement and a related phenomenon—solid metal embrittlement—can be found in the articles "Liquid Metal Induced Embrittlement" and "Solid Metal Induced Embrittlement" in *Corrosion: Fundamentals, Testing, and Protection*, Volume 13A of *ASM Handbook*, 2003.

Velocity-Accelerated Corrosion and Erosion-Corrosion

Various materials of construction for refinery and petrochemical plant service may exhibit accelerated metal loss under unusually turbulent fluid-flow conditions, which result in high values of wall shear stress either generally or locally on the exposed metal surface. Attack is usually caused by a combination of flow turbulence (mechanical factors) and corrosion (electrochemical factors) known as velocity-accelerated

corrosion or erosion-corrosion. Metal surfaces affected by velocity-accelerated corrosion will often contain grooves or wavelike marks that indicate a pattern of directional attack. Soft metals, such as copper and aluminum alloys, are often especially prone to erosion-corrosion in the presence of entrained particles in the flow path. Metals such as stainless steels depend on thin oxide films for corrosion protection. Most cases of erosion-corrosion can be minimized by proper design and/or material changes. In stainless alloys, as long as the thin passive layer remains intact, these materials can remain resistant to corrosion even at very high values of flow velocity or flow-induced wall shear stress. However, materials such as steel that form semiprotective corrosion films can exhibit increasing corrosion rate with velocity and often exhibit a very rapid increase in corrosion rate once the turbulence is great enough to remove this semiprotective film.

For example, system designs should eliminate sharp bends, because this will often significantly reduce velocity-accelerated and erosion-corrosion problems in process piping. Increasing the pipe diameter of vapor lines will usually reduce flow velocities and therefore the corrosion caused by impinging droplets of liquid. However, if this design change and resultant reduction in flow velocity also changes the flow regime to two-phase slug flow, the wall shear stress (mechanical factor) on the metal surface may actually increase despite the reduction in flow velocity. Therefore, careful use of flow modeling is required to properly assess the mechanical effects using the parameter of wall

Fig. 44 Intergranular cracking in heat-affected zone of stringer bead weld on type 304 (S30400) stainless steel pipe due to zinc embrittlement. Weld area had been covered with zinc-rich paint.

shear stress and not by the linear flow velocity. Additionally, piping immediately downstream of pressure let-down valves often must be upgraded to more corrosion-resistant alloys to increase resistance to the locally high wall shear stress to prevent accelerated attack due to high flow turbulence.

Mixed-Phase Flow. Accelerated corrosion due to mixed vapor/liquid streams is primarily found in crude and vacuum furnace headers and transfer lines of crude distillation units, in overhead vapor lines and condenser inlets on various fractionation towers, and in reactor effluent coolers of hydrocracking and hydrotreating units.

In general, increases in vapor load and mass velocity can increase the severity of high-temperature corrosion by crude oils and atmospheric residuum (reduced crude) containing naphthenic acid and/or sulfidic species (Ref 193). Under mixed-phase conditions, the least corrosive severity is associated with flow regimes in which the metal surface is completely wetted with a substantial liquid hydrocarbon layer. Corrosion is most severe with the spray flow (i.e., droplet impingement) that results from vapor velocities above 60 m/s (200 ft/s) and vapor loads above 60%. However, surprisingly severe conditions can also be produced by slug flow due to the periodic highly turbulent conditions and high wall shear stress that result with the passing of each slug of liquid in the multiphase system (see Table 1 in the article "Corrosion in Petroleum Production Operations" for a depiction of slug flow and other multiphase flow regimes).

Under these conditions, corrosion rates of certain components, such as furnace headers, furnace-tube return bends, and piping elbows, could increase by as much as 2 orders of magnitude. This phenomenon is caused by droplet impingement, which destroys the protective sulfide scale normally found on steel components, as shown in Fig. 45. Such impingement damage is usually not seen in straight piping, except immediately downstream of circumferential welds. Damage is usually in the form of sharp-edged local area corrosion. Upgrades to higher-alloy materials are usually required in piping locations that involve these types of conditions.

Corrosion damage at elbows of overhead vapor lines is often caused by droplet impingement as a result of excessively high vapor velocities. Typical impingement-type corrosion of tubes and baffles just below the vapor inlet of overhead condensers is shown in Fig. 46. As a general rule, overhead vapor velocities should be kept below 7.5 m/s (25 ft/s) to minimize impingement-type corrosion. In addition, horizontal impingement baffles can be mounted just above the top tube row of overhead condensers.

In the case of high-temperature naphthenic acid corrosion found in the petroleum distillation process, the severity of corrosion is a function of chemical variables such as the naphthenic

acid species present, the concentration of the acid (TAN value), and the presence of reactive sulfur species. Naphthenic acid tends to chemically dissolve protective sulfide films and then attack the underlying metal. Therefore, if the conditions are sufficient to produce a stable sulfide film, then naphthenic acid is of less concern. However, an additional and important factor is the wall shear stress produced by the flowing media, because high levels of wall shear stress produced by liquid or partial-vaporized hydrocarbon oils can result in sufficient mechanical action to mechanically disintegrate, damage, or otherwise remove the protective sulfide film. More information is provided in the section on "Naphthenic Acids" in this article.

Air-cooled reactor effluent coolers of hydrocracking and hydrotreating units are also prone to impingement-type corrosion. Poor flow distribution through large banks of parallel air coolers can result in excessive flow velocities in some coolers, usually those in the center. The resulting low flow velocities in the outer coolers can cause deposition of ammonium sulfide and/or chloride in these coolers; this blocks the tubes and further increases velocities in the remaining air coolers (Ref 68). This problem is aggravated by low nighttime or seasonal air temperatures, which increase deposition problems. Installation of protective sleeves (ferules) at the inlet tube end has helped to reduce attack in some cases; in others, it has only moved the area of attack to an area immediately downstream of the sleeves. Careful attention to proper

flow distribution through redesign of the inlet headers is often the only way of controlling air cooler corrosion.

The difficulty in proper assessment of flow effects and chemical effects in refinery sour water systems is the direct effect of the solution chemistry and complicated mechanical flow effects in these applications. This difficulty is made worse because most guidelines are based on experiential information obtained through optimization of specific processes and units. In these cases, it is difficult to directly relate the flow effects from one process to another process and from one operating unit to another. This is because the phase behavior and flow conditions can vary substantially with specific equipment design and unit operating conditions.

In the case of sour water corrosion, the subject of ammonium bisulfide corrosion has been addressed in the literature. In some cases, the findings are experiential in nature, resulting from surveys of hydroprocessing unit operators. In other cases, the findings are based on limited laboratory testing, but these have not adequately addressed the effect of flow. The three most influential papers are those by Piehl, Damin and McCoy, and Scherrer et al. (Ref 67, 194, 195). The most notable article in the literature is Piehl's paper that describes a survey conducted by the NACE refinery committee covering corrosion in the reactor effluent air coolers. Damin and McCoy reported results of laboratory autoclave tests over a wide range of ammonium bisulfide concentration, as shown in Fig. 47 (Ref 194). Scherrer et al. (Ref 195) present the only laboratory corrosion study documenting the effect of velocity on ammonium bisulfide corrosion (Table 11). The results of these studies and refinery experience reveal that:

- Corrosion results from the presence of ammonium bisulfide, and corrosion rate generally increases with its concentration.
- The Piehl K_p factor (mole fraction ammonia times the mole fraction H_2S in the reactor effluent) may be used to monitor the potential corrosive severity of process environments and potentially impact materials selection. However, this parameter, while good, still

Fig. 45 Accelerated high-temperature sulfidic corrosion in 500 mm (20 in.) diameter pipe of vacuum furnace outlet header due to droplet impingement at high vapor velocities

Fig. 46 Accelerated aqueous chloride corrosion below inlet nozzle of crude tower overhead condenser due to droplet impingement. Note partial loss of carbon steel baffles and localized corrosion along top of admiralty metal (C44300) tubes.

does not take into account all of the necessary factors, particularly as operating pressure increases, for accurate assessment of corrosive severity based on more recent work (Ref 5).

- Sour water corrosion involves flow velocity as a primary parameter, with excessive corrosion generally experienced at flow rates greater than 6 m/s (20 ft/s). Stainless steels may provide acceptable corrosion rates up to 9 m/s (30 ft/s), as defined primarily on service experience. However, for more rigorous assessment of corrosion performance, the wall shear stress produced by the flow needs to be examined (not just the linear flow velocity).
- Maintaining the water injection rate to result in at least 25% unvaporized (liquid) water in the effluent stream also appears important, particularly in terms of reducing the formation of deposits.
- The injected water must be free of dissolved oxygen (<50 ppb) to prevent rapid corrosion.
- Good flow distribution (in terms of vapor, liquid hydrocarbon, and water phase) is important. Therefore, tube velocities of less than 3 m/s (10 ft/s) in the air cooler can result in problems due to separation (stratification) of phases and the formation of corrosion deposits on tubes. Flow modeling can be used to more accurately assess this situation.
- Deposition of solid ammonium bisulfide salt may occur due to flow maldistribution, which starves some tubes of wash water and exacerbates both fouling and corrosion problems.
- U-bend tube designs may cause problems in the reactor effluent air cooler systems due to the possibility of velocity and wall shear stress locally accelerating corrosion in tubing bends.

More recently, a major multiclient study of both flow and chemical effects was conducted, and a comprehensive database for use in materials selection and process optimization for alkaline sour water systems was developed. The data were included in a software tool that manipulated the database for use in prediction of corrosion rates in sour water systems under various flow conditions (Ref 5). The data input screen indicates the necessary input parameters. It also contains a flow-modeling module that provides assessment of the wall shear stress for the actual system based on throughput, pipe size, and physical properties of various phases. This model calculates the resultant wall shear stress and then queries the database and interpolates between laboratory data points for these conditions to obtain the most appropriate corrosion rate predictions. The flow relationships used to assess the wall shear stress for multiphase flow are described in Ref 3 and in the article "Corrosion in Petroleum Production Operations" in this Volume.

Cavitation damage is a fairly common form of erosion-corrosion often found to affect pump impellers or hydraulic turbine internals.

Cavitation is caused by collapsing gas bubbles at high-pressure locations; adjacent metal surfaces are damaged by the resultant hydraulic shock waves and the mechanical stress produced locally on the metal surface. Cavitation damage is usually in the form of loosely spaced pits that produce a roughened surface area. The damage can be produced from the mechanical disintegration of the protective corrosion films, or it can take the form of metal deformation and removal. In the latter case, subsurface metal shows evidence of mechanical deformation (e.g., slip bands and local cold working). As a general rule, cast alloys are likely to suffer more damage than wrought versions of the same alloy due to their typically coarser grain structure and alloy segregation. Ductile materials, such as wrought austenitic stainless steels, have the best resistance to cavitation because their resistance is based on the thin chromium oxide film on the metal surface, which is very tenacious and resistant to mechanical damage, except in the most extreme conditions or from impact of erosive particles. Damage can be reduced by design or operational changes, material changes, and sometimes, the use of corrosion inhibitors. Smooth finishes on pump impellers help to reduce this type of damage. Some coatings can be beneficial. Design changes with the objective

of reducing pressure gradients in the flowing liquid are most effective.

Entrained Particles. Accelerated corrosion due to entrained catalyst particles can occur in the reaction and catalyst regeneration sections of catalytic cracking units. Furthermore, refineries involved with processing of hydrocarbons derived from oil or tar sands may be exposed to entrained fine particulates. Local erosive attack of a process piping system is shown in Fig. 48. Refractory linings are required to provide protection against oxidation and high-temperature sulfidic corrosion as well as erosion by catalyst particles, particularly in cyclones, risers, standpipes, and slide valves. Stellite or ceramic hardfacing can be used on some components to protect against erosion. However, those hardfacing materials that involve a metal matrix can be susceptible to corrosion damage if this matrix material is not resistant to corrosion in the process medium and its contaminants. Additionally, fine particles (<20 μm) can result in erosion of the metal matrix. Therefore, the best hardfacing materials are typically those with high tungsten carbide or ceramic particle loading and a minimum of metal-matrix binder.

When there are no erosion problems and when protective linings are impractical, austenitic stainless steels such as type 304 (S30400) can be used. Cyclone dip legs, air rings, and other internals in the catalyst regenerator are usually

Fig. 47 Effect of ammonium bisulfide concentration on corrosion at 93 °C (200 °F) of several materials in simulated refinery sour water environment

Table 11 Laboratory data on corrosion of carbon steel versus ammonium bisulfide concentration and liquid-phase velocity

Ammonium bisulfide content		Average corrosion rate, mm/yr (mils/yr), at 60 to 100 °C (140 to 212 °F)			
		Fluid velocity			
g/L	wt%	3.5 m/s	(11.4 ft/s)	6.5 m/s	(21.3 ft/s)
40	4	0.2–0.3	(8–12)	0.3–0.4	(12–16)
100	10	0.3–0.4	(12–16)	0.5–0.6	(20–24)
200	20	0.6–0.8	(24–32)	1.0–1.2	(40–48)

made of type 304 (S30400) stainless steel, as is piping for regenerator flue gas. The main fractionation tower is usually made of carbon steel, with the lower part lined with a ferritic or martensitic stainless steel containing 12% Cr such as type 405 (S40500) or 410 (S41000). Slurry piping between the bottom of the main fractionation tower and the reactor may receive an additional corrosion allowance as protection against excessive erosion.

Corrosion Control

A component in refinery or petrochemical service will require replacement when:

- Corrosion or other deterioration has made it unfit for further service.
- It no longer performs satisfactorily, although it may still be operational.
- It has become completely nonoperational.

Based on the results of a failure analysis, certain corrective measures can be implemented. These include, for example, the use of alternative materials of construction, changes in equipment design and process conditions, the use of corrosion inhibitors, and the application of protective coatings and linings.

Materials Selection. The most common method for preventing repeated failures is selection of improved metals or alloys. If a given piece of equipment fails every other year or so, substitution of a more highly alloyed material or alternative alloy that provides better performance can invariably be justified. In contrast, there is no justification for replacing a carbon steel tank with one made from a more corrosion-resistant alloy if the tank corroded out after 35 years of service (unless, of course, all of the corrosion occurred during a short period near the end of its life).

Design Changes. Proper design of equipment is usually as important as proper selection of material. Design changes should involve consideration of changes in strength requirements, changes in material, and the need for additional allowances for corrosion, depending on past experience. Certain simple design rules should be followed to reduce corrosion-related problems:

- Welded joints can be substituted for flanged joints to minimize crevice corrosion.
- Equipment can be modified to permit easy cleaning and draining.
- Piping for certain equipment, such as pumps, can be modified to allow bypassing or replacement during service.
- Mechanical and vibrational stresses can be minimized by providing additional supports to avoid stress-related failures.
- Sharp bends in piping can be realigned to prevent erosion-corrosion.
- Heat exchangers can be modified to reduce temperature gradients that cause high stresses and also accelerate corrosion problems.

Further information on design considerations is available in the article "Designing to Minimize Corrosion" in *Corrosion: Fundamentals, Testing, and Protection*, Volume 13A of *ASM Handbook*, 2003.

Process changes that can be considered for reducing corrosion and other failures include the following:

- Temperature can be decreased to decrease corrosion rates.
- Concentrations of critical corrosive species can be adjusted.
- Flow velocity can be limited to prevent erosion-corrosion.
- Oxygen (air) can be removed by the use of scavenging chemicals.
- Water entry can be controlled by installation of calcium chloride drying equipment, settling drums, or demister screens.

Changing the concentration of corrosive contaminants in hydrocarbon streams is usually effective. Certain catalysts, such as hydrofluoric acid, are virtually inert when highly concentrated, but when diluted by water, they become extremely corrosive. Reducing the amount of acid entrained in hydrocarbon streams invariably reduces corrosion problems.

Changes in the flow regime of mixed vapor/liquid streams as a result of velocity changes can have a pronounced effect on corrosion. Very high velocities can produce problems associated with droplet impingement, and intermediate velocities with high liquid loading can result in highly turbulent slug flow. Also, stagnant or low flow conditions should be avoided, because stratified conditions can result in water wetting of the metal surface without the benefit of a protective hydrocarbon film. These conditions must also be avoided with metals that form passive oxide films, such as stainless steels. Minimum flow rates need to be maintained even when throughput is reduced.

Deaeration finds widespread application in the treatment of boiler feed water. The corrosion of certain nickel alloys by hydrofluoric acid can be controlled by excluding air. However, metals that depend on passive oxide films for corrosion resistance may actively corrode in certain environments if air is excluded.

Corrosion Inhibitors. Filming-amine corrosion inhibitors are added in small concentrations to various process streams to help control corrosion. Filming-amine inhibitors become ineffective at temperatures above approximately 175 °C (350 °F)—not because they decompose, but because the rate of desorption begins to exceed the rate of adsorption. The inhibitors are primarily used to protect overhead condensing equipment. Water-dispersible types contain surfactants to allow addition to streams that contain excess water. In general, filming-amine inhibitors are continuously injected at a rate that is just sufficient to maintain protection, which varies from compound to compound and with formulation additives. Higher-than-normal dosages

are required for several days to establish a protective film after inhibitor injection has been interrupted (for example, because of pump failure) or after a shutdown. Most filming-amine inhibitors will tend to solubilize prior corrosion products; this can lead to fouling problems in downstream equipment. In amine units, these inhibitors usually cause foaming problems. Detailed information is available in the articles "Corrosion Inhibitors for Oil and Gas Production" and "Corrosion Inhibitors for Crude Oil Refineries" in *Corrosion: Fundamentals, Testing, and Protection*, Volume 13A of *ASM Handbook*, 2003.

Protective Coatings. Although most refineries and petrochemical plants do not rely on organic coatings for corrosion control, because a fire would immediately destroy these, extensive use is made of metallic cladding and refractory linings in process equipment. Cladding is usually performed at the mill by rolling a relatively thin sheet of a corrosion-resistant metal or alloy to a thicker base metal at elevated temperatures. The finished product will exhibit a fully bonded, metallurgical joint. Clad plates can be formed and fabricated into vessels or piping by welding the joints of the base metal and overlaying the welds. Thin sheet strips of corrosion-resistant alloy can be attached by spot welding in the field to protect an unclad vessel. This process is known as strip lining. For long-term service, however, cladding tends to be more reliable than strip lining. Strip lining can become a source of problems with process streams that contain hydrogen at elevated temperatures and pressures or that evolve hydrogen because of corrosion. In either case, pockets of hydrogen can build up behind the lining and cause it to fail. Cladding by explosive bonding is primarily used for new construction to attach titanium or nickel alloy overlays.

Overlays of corrosion-resistant alloys can also be attached in the form of adjacent weld beads. For example, reactor vessels for hydrocracking and hydrotreating units are protected against high-temperature sulfidic corrosion with a weld overlay of type 347 (S34700) stainless steel.

Thermal sprayed metallic and ceramic coatings, as a rule, have not been extensively used in refinery and petrochemical plant applications, because such coatings have not been very reliable. However, improved methods of applications that provide higher density and lower impurities are now available and finding increased use in selective areas.

Diffusion coatings, particularly aluminized coatings, have been highly successful as an alternative approach to controlling high-temperature sulfidic corrosion of carbon steel and low-alloy steel components. Aluminizing not only provides resistance to high-temperature sulfidic corrosion but also reduces scaling, carburization, coking, and erosion problems (Ref 196). Aluminized components are not necessarily less costly than those made of higher-alloy steels or stainless steels, and a detailed cost

analysis is usually required. Aluminizing is a proprietary process in which steel components are packed into a retort and exposed to aluminum vapor at a temperature above approximately 925 °C (1700 °F). The aluminum diffuses into the steel, and this forms a true metallurgical alloy containing over 50% Al at the surface.

Other methods for forming a corrosion-resistant iron-aluminum layer on steel surfaces include flame spraying and hot dipping, either with or without subsequent diffusion heat treatments. As a rule, these methods have been less effective than aluminizing, primarily because of nonuniform thickness, porosity, and holidays (Ref 197).

The aluminizing of carbon steel or low-alloy steel components typically increases their resistance to high-temperature sulfidation by 2 orders of magnitude (Ref 198). However, the diffused iron-aluminum layer is only 0.08 to 0.4 mm (3 to 15 mils) thick, depending on the base alloy, and can be readily damaged by mechanical (tube drilling for coke removal) or chemical means (acid or caustic cleaning). Aluminized components also require special fabrication techniques, including welding and roller expanding. Distortion and shrinkage during aluminizing can be a problem with some components.

A variety of processes for applying protective coatings are discussed in the Section "Methods of Corrosion Protection" in *Corrosion: Fundamentals, Testing, and Protection*, Volume 13A of *ASM Handbook*, 2003. Methods for applying weld claddings are discussed in various articles in *Welding, Brazing, and Soldering*, Volume 6 of *ASM Handbook*, 1993 (see, in particular, the articles in the Section "Solid-State Welding, Brazing, and Soldering Processes").

Refractory Linings. Refractory materials are used in refineries and petrochemical plants as linings to protect steel from thermal degradation, erosion damage, and both low- and high-temperature corrosion. Unlike thin organic linings and coatings, refractory linings are applied in thicknesses of 25 to 100 mm (1 to 4 in.) or more. Metal wire reinforcement is used to help hold the lining in place.

Portland cement/sand is the lining that is most commonly used to protect steel against mild corrosives. This lining (frequently called gunite or shotcrete, after the application technique) has been used in refineries for more than 60 years. The primary application is sour water service with a pH value between 4 and 8. The material is low cost, and the application is straightforward. The mixture is applied with a pneumatic gun that shoots the premixed cement, sand, and water onto the vessel surface. A chicken-wire metal reinforcement is usually provided at the midthickness. As with any other concrete, the lining must be cured before it is placed into service. During ambient-temperature curing, shrinkage cracks may occur, but they are not detrimental to the serviceability of the lining. Acidic water entering the cracks is neutralized by the alkalinity of the concrete and is trapped in the crack. However, continuing acid attack

will result in gradual loss of thickness (much like corrosion), and aggregate, which is carried away in the process fluid, may cause erosion or plugging in downstream equipment, such as filters, pumps, and valves.

For highly acidic solutions or for higher temperatures, more resistant cements and aggregate such as lumnite-haydite need to be used. These special acid-resistant cements, which are based on silicate, furane, phenolic, and sulfur compounds, are used for highly acidic services but at the cost of reduced resistance to alkaline solutions. In addition to gunning, these cements can be applied as thinner coatings by troweling.

For hot, highly acidic solutions, acid-proof brick linings can be used. The essential components of such a lining are a membrane lining against the steel shell, topped with brick-and-mortar construction. A membrane is placed between the bricks and the steel shell, because brick-and-mortar construction is inherently porous and subject to capillary leakage. Membrane materials need not be completely immune to attack by the corrosive, because any swelling of the membrane will tend to seal off the bottoms of the capillary channels. Furthermore, the brick lining does provide thermal insulation, which reduces the temperature and therefore the aggressiveness of the corrosive. Typically, one course of 115 mm (4.5 in.) thick brick raises the temperature limit of a membrane material by approximately 30 °C (54 °F), and two courses by approximately 50 °C (90 °F).

The membranes range from thermoplastic resins and elastomers to sheet or bonded lead linings, depending on the corrosive handled and the need to accommodate relative movement between the shell and the brick lining. Ceramic brick is satisfactory for all common operating conditions and corrosives, except strong alkalis, hydrofluoric acid, and fluorides, which require carbon brick. As a rule, acid-proof brick linings have limited applications in refineries and petrochemical plants, the principal uses being storage tanks for sulfuric acid. They are seldom used for pressure vessels, especially those that operate at elevated temperatures and pressures.

Heat-resistant linings can reduce the cost of pressure vessels that will operate at temperatures above 345 °C (650 °F). Allowable stresses, given in the ANSI/ASME Boiler and Pressure Vessel Code, Section VIII, for the design of carbon steel vessels, decrease with increasing temperatures. Because the maximum permissible temperature for carbon steels is 510 °C (950 °F), alloy steels must be used above this temperature. A heat-resistant lining, by reducing the metal temperature, will reduce the required wall thickness of carbon steel vessels, such as reactors. Alternatively, heat-resistant linings allow the use of carbon steel vessels at higher temperatures, such as reactors in fluid catalytic cracking units. For either of these applications, the integrity of the lining is important, because loss of insulation can result in areas of the vessel reaching temperatures above the acceptable mechanical design limit (hot spots). When hot

spots are found, temperatures can be reduced by air blowing or steam sprays. If this is not effective, the unit must be immediately taken out of service for repair of the lining. Properly applied linings will be effective for extended time periods and require repairs only during normally scheduled shutdowns.

The heat-resistant and insulating linings used in pressure vessels are refractory materials that are applied as monolithic linings by pneumatic gunning, casting, or hand packing. The most common types are the hydraulic-setting castable refractories. Their ease of application, generally good performance, and variety of strength and insulating characteristics make them versatile high-temperature materials. The quality of the applied castable material depends on the product quality as produced by the manufacturer, the experience of the applicator, and the manner in which heat is first applied to the material after it is installed. Erosion-resistant linings are relatively thin (40 mm, or 1.5 in.) layers of dense refractories that are supported by V-anchors or hexmesh welded directly to the vessel shell. To improve the serviceability of V-anchored linings, metal fibers are often added to the refractory mix before placement.

Catalytic cracking units, with their associated cyclones, transfer lines, and slide valves, represent the single largest application of refractories in refineries (Ref 199). The regenerator vessels, and sometimes the reactors, are lined with 100 to 150 mm (4 to 6 in.) of refractory concrete, which must withstand oxidizing (regenerator) or reducing (reactor) conditions at 540 to 760 °C (1000 to 1400 °F). The moving catalyst bed produces mild erosion, and mechanical or thermal spalling is frequently encountered. Cyclones and catalyst transfer lines are usually subjected to extreme erosion from fluidized catalyst at temperatures between 315 and 760 °C (600 and 1400 °F). Transfer lines are subjected to heavy loadings of catalyst at velocities of 7.5 to 15 m/s (25 to 50 ft/s). Slide valves in transfer lines and standpipes are subject to severe erosion but must maintain their original thickness so they can control catalyst flow. Care must be exercised in designing the slide valve because of thermal expansion differentials. Plug valves have more tolerance for thermal expansion differentials and are frequently lined with refractory.

Because operating conditions in reformer reactors include hydrogen-rich vapors at approximately 500 °C (950 °F), special care is required in designing refractory liners because of the increased thermal conductivity of hydrogen-saturated refractories. Reformers in hydrogen and ammonia plants operate at 1100 to 1370 °C (2000 to 2500 °F) and therefore require refractories of very low silica content. Furnaces are typically lined with castable refractory or insulating fire brick. Thermal shock and temperature cycling are the primary agents of attack. Mechanical movement, nut blasting, and similar forces also contribute to deterioration. Floors are usually made of dense refractory concrete or fire

brick in order to resist foot traffic and mechanical impact during turnarounds. Stacks and breechings for most types of refinery units have similar service requirements: strength at high temperatures and resistance to corrosion, erosion, and spalling. Temperatures range from 205 to 815 °C (400 to 1500 °F), and the flue gas may contain catalyst, sulfur oxides, H₂S, or carbon monoxide. Water or steam may be injected into the gas stream to control temperature.

If conditions are mild, with temperatures below 540 °C (1000 °F) and little or no erosion, insulating or semiinsulating refractory concrete on independent anchors makes a serviceable lining. More erosive conditions may require the use of dense high-strength refractory castable.

High-sulfur fuels generate sulfuric acid in the cooler zones of stacks and breechings where temperatures drop below the acid dew-point, ranging from 150 to 175 °C (300 to 350 °F). Acid attacks many conventional castable refractories containing calcium aluminate cement. The alkali-silicate and some calcium-aluminate base materials are moderately acid resistant and will withstand condensing flue gas vapors. For many furnace stack linings, densely applied semiinsulating refractory concrete is satisfactory.

Incinerators operate at temperatures as high as 1540 °C (2800 °F) and are particularly susceptible to slag and fly-ash attack, because they often burn waste products. Problems can be expected with fluids containing alkalis and transition metals. Thermal shock can be a problem if water is injected to control temperatures or if the burner unit is allowed to cycle on and off several times a day, with periods of cooling in between. Castable phosphate-bonded alumina is probably the best material for this type of service. Additional information on refractory linings can be found in the article "Chemical-Setting Ceramic Linings" in *Corrosion: Fundamentals, Testing, and Protection*, Volume 13A of *ASM Handbook*, 2003.

Use of Process Control and Corrosion Monitoring. One of the problems associated with reducing the costs of corrosion in refinery operations is that corrosion is commonly dealt with in a historical sense, after the damage has occurred. In this light, corrosion measurements are usually relegated into spot checks and maintenance functions. Monitoring data are recorded off-line and not viewed real-time with the process conditions that often initiate high-level corrosion activity. However, recent innovations in monitoring technology along with an evolving purpose of the refinery corrosion engineer in the new online, real-time world of refinery process control/optimization and asset management are leading the way to change for those that embrace, utilize, and promote these new corrosion-monitoring technologies.

Online, real-time technologies are commonplace for refinery process control and have only recently entered the corrosion-monitoring realm. They have increased the accuracy of data and their relevance and value to the ultimate goal of

increasing productivity by reducing corrosion damage, failures, and unplanned outages, thus decreasing downtime and increasing run time. They have also provided online connectivity for corrosion engineers, bringing them in closer contact with the frontline people that control processes and manage these facilities. This makes their role much more relevant. Under this new paradigm, corrosion becomes another real-time process variable.

Historical approaches for off-line measurement methods also include such general corrosion-monitoring techniques as electrical resistance (ER) and linear polarization resistance (LPR), as discussed in ASTM G 96 (Ref 200). These systems are able to operate in a stand-alone mode providing "spot" corrosion data via battery-powered, plant-mounted instruments, often with logging capability. These techniques can help in determining inspection frequencies based on the average mass loss corrosion rates obtained from these corrosion-monitoring techniques.

Modern field corrosion monitoring now includes a broad range of techniques used to evaluate the degradation of metallic materials. These techniques can be divided into two distinct groups, namely those providing indications of the cumulative damage sustained (retrospective) and those providing indications of the prevailing corrosion rate (usually online and continuous). These techniques are applicable with virtually all metallic materials and are commonly grouped as follows:

- *Cumulative loss techniques:* Weight loss coupons, ER monitoring, ultrasonic thickness measurement, and other nondestructive examination methods (e.g., radiography). The cumulative loss techniques will only show signs of change when sufficient corrosion has been sustained to cause a change in the bulk material properties. As such, most are used offline and do not provide real-time data, requiring measurement cycles of days to weeks.
- *Corrosion rate techniques:* LPR, harmonic distortion analysis (HDA), and electrochemical noise (EN) monitoring methods. The corrosion rate techniques have a much higher resolution and short response time and have been developed to provide a fast assessment of the electrochemical rate processes taking place at the metal/environment interface. Measurements using these techniques take only a few minutes (Ref 201).

Advances in automated monitoring systems have made it possible to incorporate multiple measurements into a single instrument, thereby increasing accuracy to the point of being able to make quantitative measurements [e.g., LPR corrosion rate with actual measured *B* value (Stern-Gerry factor) correction from HDA] and being able to differentiate the modality (pitting versus uniform corrosion) of the corrosion process (e.g., use of EN). Furthermore, this can

be done on a time scale of minutes, which is consistent with modern process control approaches. This latter point is extremely important, because it now is possible to provide quantitative corrosion rate and modality information and deliver them via the same (and existing) communications protocols (4–20 mA, RS-485, RS-232, and HART) that are already in place and used to acquire process variables through field-based system control and data acquisition systems or plant-distributed control systems.

The importance of the aforementioned advances is that the corrosion engineer can now be "plugged into" the same online, real-time channel that is used for process control and optimization and facilities asset management. Corrosion data are automatically commingled and displayed with process data. The corrosion engineer is no longer relegated to a stand-alone function. He/she can see the same real-time process data that the process engineer sees, and the process engineer has access to the online corrosion rate that the corrosion engineer sees, enabling uses of these data together as key performance indicators. Figure 49 illustrates this interrelationship. Both engineering functions can now work together in a new way (Fig. 49) (Ref 201).

- The process engineer uses the corrosion signal as another variable that needs to be optimized (e.g., minimize asset damage, increase production while controlling damage to acceptable levels, extend allowable run time, and manage process to minimize inspection requirements).
- The improved connectivity gives the plant operator immediate access to both corrosion data and the corrosion engineer, who can immediately provide valuable input regarding the impact of process upsets. The corrosion engineer can also be included in process optimization studies, because corrosion is now another process variable. This is a quantum leap for the corrosion engineer to a much more value-oriented position in the company.

Process Optimization Study in a Hot Hydrocarbon Stream with 1 to 2% Corrosive Water. This example involves monitoring performed at a petrochemical operation where much of the plant is constructed of carbon steel and type 304L and 316L stainless steels (Ref 202). Decades of debottlenecking and other process modifications had produced corrosion problems. After a year of unsuccessful efforts to untangle their process problems, an online, real-time electrochemical corrosion-monitoring system was installed. For the first time, materials engineers, process engineers, and plant operators were able to see immediate changes in corrosion behavior caused by specific variations in process parameters and work together to identify process modifications and remedial actions.

Realizing that this environment was mostly a nonconductive organic phase, and the entry points for probes were mostly located on vertical pipe runs, custom-designed probes were installed at ANSI flange joints in a piping system where the most severe corrosion had been observed. Based on the results of the initial process evaluation, which required several weeks, five predominant factors were identified

that related directly to the chemical aggressivity of the plant environment. These included:

- An upstream vessel was on an automatic pump-down schedule, so that it pumped its contents into a reactor approximately once per hour. Every time the vessel pumped down, the corrosiveness of the larger stream increased.

- Operations had reduced the concentration of a particular neutralizing chemical in the process. Contrary to what was expected, it was found that increasing the feed rate of the neutralizer increased corrosion rates rather than reducing them (Fig. 50). This new information helped to reduce corrosion rates and also to provide process engineers with new insight into the chemistry of the process.
- Following review of the corrosion data for the first time, a plant technician pointed out that an increase in corrosion rate of the type 304L electrodes occurred right after a new batch of catalyst was mixed.
- Further investigations indicated that the corrosion rate also varied quite significantly with process and operational events. These included noting that the corrosion rate of carbon steel correlated with the quantity of a key gaseous chemical used in the process.
- In another process stream, short-term spikes to very high corrosion rates were observed intermittently but consistently, week after week. Later, it was determined that the corrosion rate spikes coincided with the pumping of laboratory samples back into the process upstream operations. This subsequently led to changes in how the lab samples were disposed of. This stopped the corrosion spikes.

Ultrasonic thickness measurements were taken on various parts of the piping in the vicinity of the corrosion-monitoring points. These indicated an average corrosion rate of 0.075 mm/yr (2.965 mils/yr) over a 16 month period. These data agreed very well with the 0.074 mm/yr (2.9 mils/yr) corrosion rate predicted by online, real-time corrosion measurements described in Ref 201 to 204 and discussed in the article "Corrosion in Petroleum Production Operations" in this Volume.

Appendix: Industry Standards

James Skogsberg and Ned Nicolls,
Chevron Texaco; Russell D. Kane,
Honeywell Process Solutions,
Honeywell International, Inc.

THE APPLICABLE STANDARDS for materials used in corrosive service conditions in upstream (oil and gas drilling, production, and gathering) and downstream petroleum service (gas processing and oil refining) are reviewed. Applicable and commonly used standards related to corrosion control and materials selection are presented. These are commonly referenced by corrosion and materials engineers to define and apply corrosion control through specification of equipment and/or material, control of composition and material processing for metallic

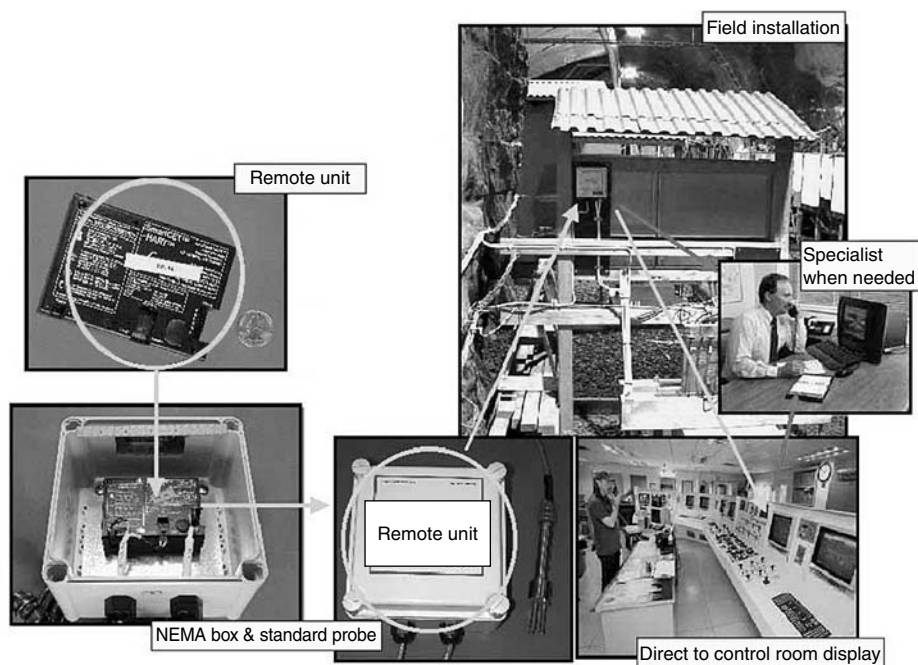

Fig. 49 Montage showing interrelationship between a petrochemical plant process engineer and corrosion/materials specialist using online, real-time corrosion monitoring. Distributed corrosion-monitoring hardware provides a preprocessed data signal at point of monitoring. This, in turn, provides simultaneously an alarmed measurement-and-control signal in the control room and access to the same information on the engineer's workstation. Source: Ref 201

and nonmetallic materials of construction (alloys, elastomers, plastics, and composites), description of service conditions and requirements, application of cathodic protection, definition of applicable fabrication or construction methods, definition of performance test methods, and for definition of materials requirements for exposure to H₂S service conditions.

Selection of materials to resist all forms of environmentally assisted cracking mechanisms in sour (H₂S-containing) service environments is an important aspect of both upstream and downstream petroleum service applications. These forms of cracking include:

- Sulfide stress cracking (SSC) of steels
- Hydrogen-induced cracking (HIC) of steels
- Stress-oriented hydrogen-induced cracking (SOHIC) of steels
- Stress-corrosion cracking (SCC) of corrosion-resistant alloys (CRAs)

Two documents that deal specifically with SSC and SCC are NACE MR0175/ISO 15156, "Petroleum and Natural Gas Industries—Materials for Use in H₂S-Containing Environments in Oil and Gas Production" which applies to upstream service applications; and NACE

MR0103, "Materials Resistant to Sulfide Stress Cracking in Corrosive Petroleum Refining Environments," which applies for downstream refinery applications.

An intensive standards-writing effort recently resulted in the technical alignment NACE standard MR0175, "Metals for Sulfide Stress Cracking and Stress Corrosion Cracking Resistance in Sour Oilfield Environments," and ISO 15156, "Petroleum and Natural Gas Industries—Materials for Use in H₂S-Containing Environments in Oil and Gas Production." NACE MR0175/ISO 15156 gives requirements and recommendations for the selection and qualification of carbon and low-alloy steels, corrosion-resistant alloys, and other alloys. It is specially directed toward materials used in oil and natural gas production and natural gas treatment plants in H₂S-containing environments, whose failure could pose a risk to the health and safety of the public, to personnel, or to the environment. It can be applied to help avoid costly corrosion damage to the equipment itself. NACE MR0175/ISO 15156 consists of three standards, available through NACE as a complete package:

- *Part 1*: General principles for selection of cracking-resistant materials

- *Part 2*: Cracking-resistant carbon and low-alloy steels, and the use of cast irons
- *Part 3*: Cracking-resistant CRAs and other alloys

Similarly, an intensive standard-writing effort has also taken place within NACE, with the goal to define requirements for materials used in refinery applications relative to SSC. The resultant standard (NACE MR0103) acknowledges that while some refinery sour service requirements are similar to those found in upstream applications, there are many aspects of refinery service that require special considerations when it comes to guidelines for materials selection in H₂S service. This new document for the first time addresses the specific requirements of materials in refining application for resistance to SSC.

Materials of construction and other documents that deal with forms of H₂S attack and corrosion are included in the tables of standards and reference documents that follow. The standards and documents for the upstream and downstream portions of the petroleum industry are in Tables 12 and 13, respectively. Some standards are applicable to both. A list of sponsoring organizations (Table 14) provides source information.

External Corrosion of Oil and Natural Gas Pipelines

John A. Beavers and Neil G. Thompson, CC Technologies

PIPELINES play an extremely important role throughout the world as a means of transporting gases and liquids over long distances from their sources to the ultimate consumers. The general public is not aware of the number of pipelines that are continually in service as a primary means of transportation. A buried operating pipeline is rather unobtrusive and rarely makes its presence known except at valves, pumping or compressor stations, or terminals. In the United States, there were approximately 217,000 km (135,000 mi) of hazardous liquid transmission pipelines, 34,000 km (21,000 mi) of crude oil gathering pipelines, 483,000 km (300,000 mi) of natural gas transmission pipelines, and 45,000 km (28,000 mi) of natural gas gathering pipelines in 2000 (Ref 1–3). There were approximately 60 major natural gas transmission pipeline operators and 150 major hazardous liquid pipeline operators in the United States in 1998 (Ref 4).

The first oil pipeline, which was 175 km (109 mi) in length and 152 mm (6 in.) in diameter, was laid from Bradford to Allentown, PA in 1879 (Ref 5). Since the late 1920s, virtually all oil and gas pipelines have been made of welded steel. Although the first cross-country pipeline that connected some major cities was laid in 1930, it was not until World War II that large-scale pipelines were laid connecting different regions of the country. In the 1960s, larger-diameter pipelines ranging from 813 to 914 mm (32 to 36 in.) were built. Discovery of oil on Alaska's North Slope resulted in the construction of the country's largest pipeline, the Trans-Alaska Pipeline System, with a 1219 mm (48 in.) diameter and 1287 km (800 mi) length. Demand continues to add more miles of pipelines.

Table 1 provides a summary of the major accidents reported to the U.S. Department of Transportation by the operators for the 6-year period between 1994 and 1999 (Ref 6). The data show that for transmission pipeline systems (both hazardous liquid and natural gas), approximately 25% of all reported accidents were due to corrosion. Of the hazardous liquid pipeline accidents caused by corrosion, 65% were due to external corrosion and 34% were due to internal corrosion. For natural gas transmission pipeline accidents,

36% were caused by external corrosion and 63% were caused by internal corrosion. For natural gas distribution pipeline accidents, only approximately 4% of the total accidents were caused by corrosion, and the majority of those were caused by external corrosion. The accidents reported in Table 1 are for major accidents that resulted in injury, fatality, or more than \$50,000 in property damage. In addition to the reportable accidents, an average of 8000 corrosion leaks per year are repaired on natural gas transmission pipelines (Ref 7), and 1600 spills per year are repaired and cleaned up for liquid product pipelines.

In a summary report for incidents between 1985 and 1994, corrosion accounted for 28.5% of pipeline incidents on natural gas transmission and gathering pipelines (Ref 8). In a summary report for incidents between 1986 and 1996, corrosion accounted for 25.1% of pipeline incidents on hazardous liquid pipelines (Ref 9). These values correspond very well to the statistics for 1994 to 1999 presented in Table 1.

Given the implications of pipeline failures and the role that external corrosion plays in these failures, it is apparent that proper corrosion control can have a major impact on the safety, environmental preservation, and the economics of pipeline operation.

The vast majority of underground pipelines are made of carbon steel, based on American Petroleum Institute API 5L specifications (Ref 10). Typically, maximum composition limits are specified for carbon, manganese, phosphorous,

and sulfur. In some cases, other alloying elements are added to improve mechanical properties. Composition and tensile requirements for common line pipe steels are shown in Table 2.

These steels have inadequate alloy additions to be considered corrosion resistant and undergo

Table 1 Summary of corrosion-related accident reports on hazardous liquid, natural gas transmission, and natural gas distribution pipelines from 1994 to 1999

Category	Pipeline system type		
	Hazardous liquid transmission	Natural gas transmission	Natural gas distribution
Total accidents	271	114	26
due to corrosion (1994–1999)			
Total accidents (1994–1999)	1116	448	708
Total accidents due to corrosion, %	24.3	25.4	3.7
Corrosion accidents due to external corrosion, %	64.9	36.0	84.6
Corrosion accidents due to internal corrosion, %	33.6	63.2	3.8
Corrosion accidents cause not specified, %	1.5	0.9	11.5

Product specification level 1, Ref 10

a variety of corrosion failure modes/mechanisms in underground environments, including general corrosion, pitting corrosion, and stress-corrosion cracking (SCC).

The terms general corrosion and pitting corrosion are used rather loosely when describing the morphology of underground corrosion. The classical pitting often associated with passive metals (such as stainless steels) is typically not observed on underground pipelines, with the possible exception of cases where microbial activity is involved. Likewise, true general corrosion, where there is uniform metal loss, such as observed with carbon steel in a concentrated acid, is not commonly found on underground pipelines. The most common morphology of corrosion on underground pipelines is uneven metal loss over localized areas covering a few to several hundred square inches (Fig. 1). The most common mechanism causing this corrosion is referred to as differential corrosion cells. Microbes and stray direct current (dc) in the soil also can affect underground corrosion.

Because of the relatively poor corrosion resistance of line pipe steels in underground environments, a combination of mitigation strategies consisting of coatings and cathodic protection (CP) is required. In this article, the most common causes and contributing factors for corrosion and SCC, as well as prevention, mitigation, detection, and repair are discussed.

Fig. 1 Example of external corrosion of an underground pipeline. Lower quadrant of pipeline shown after coating removal and abrasive cleaning

Fig. 2 Differential corrosion cell created by differences in soils. Arrows indicate the direction of ionic and electronic current flow.

Differential Cell Corrosion

In the case of true general corrosion of a metal, the oxidation and reduction reactions occur physically at or very near the same location on a metal. At any given moment, one atom is being oxidized while the reduction reaction is occurring at an adjacent atomic site. Corrosion of a metal in an acid solution is a common example of this type of behavior. It is also possible for the oxidation and reduction reactions to be separated on a metal surface, where the metal oxidation occurs predominantly at one site while the reduction reaction occurs predominantly at another site. This is referred to as a differential corrosion cell. Underground corrosion of pipelines and other structures is often the result of differential corrosion cells of which a variety of different types exist. These include differential aeration cells, where different parts of a pipe are exposed to different oxygen concentrations in the soil, and cells created by differences in the nature of the pipe surface or the soil chemistry. This behavior is sometimes obvious when excavating an old, bare pipeline in which some areas are in excellent condition but other areas only a few feet away are severely corroded.

A **differential aeration cell** is probably the most common corrosion cell found on pipelines or other underground structures. One area of the pipeline is exposed to higher concentrations of oxygen and becomes the cathode in the cell, while another part of the structure is oxygen deficient and becomes the anode. Electrical current leaves the metal surface at the anode, increasing the corrosion rate, and flows to the oxygenated cathodic area, decreasing the corrosion rate. Differential aeration cells as well as other corrosion cells can be autocatalytic in that the chemical and electrochemical reactions, as well as ion migration, tend to produce conditions that promote the continuation of the cells. At the anode, the metal ions produced by the corrosion reactions hydrolyze (react with water), reducing the local pH. Corrosive negative halide ions migrate to the anodic sites to maintain charge neutrality. Both of these processes increase the corrosivity at the anodic sites. At the cathodic

sites, the reduction reactions increase the pH and improve the protective nature of the corrosion films.

Differences in soil properties, variation in the moisture content of the soil, the depth from the surface or oxygen barriers such as paved roads can produce differential aeration cells. An example is illustrated in Fig. 2, which shows a pipeline passing through two dissimilar soils. The corrosion potential of the pipeline in the clay soil is more negative than the corrosion potential in the sandy soil, resulting in an increase in the corrosion rate of the pipe in the clay and a decrease in the sand. Factors other than differences in the oxygen concentration of the soil can produce a differential corrosion cell such as the one shown in Fig. 2. For example, differences in the pH, or the concentration of aggressive ions such as chlorides in the soil, can produce differential corrosion cells.

Galvanic corrosion is another example of a differential corrosion cell. In the case of galvanic corrosion, the potential difference is created by the presence of different metals. Different metals have a different corrosion potential in a given environment. An example is the galvanic series for metals in soils, shown in Table 3 (Ref 11). When these metals are electrically coupled, the metal with the most positive corrosion potential is cathodically polarized, reducing its corrosion rate, while the more negative member of the couple is anodically polarized, increasing its corrosion rate. Galvanic corrosion can be very detrimental to an underground structure. Examples include the corrosion of iron in contact with copper or stainless steel fittings. However, galvanic corrosion can be used as an effective means of CP, as described in the section on CP.

The surface films present on a metal also can alter the corrosion potential and cause differential cell corrosion. For example, mill scale is created on line pipe steel during the manufacturing process (hot rolling) and, if not removed, the mill-scale-coated steel will act like

Table 3 Practical galvanic series and redox potentials of metals and alloys in neutral soils and water

Material	Potential (CSE)(a), V
Most Noble	
Carbon, graphite, coke	+0.3
Platinum	0 to -0.1
Mill scale on steel	-0.2
High-silicon cast iron	-0.2
Copper, brass, bronze	-0.2
Low-carbon steel in concrete	-0.2
Lead	-0.5

a dissimilar metal in contact with non-mill-scale-coated pipe steel. The potential of the bare pipe steel surface will be more negative (active) than the mill-scale-coated surface, resulting in severe corrosion of the bare steel surface in low-resistivity soils. A similar condition can occur when new steel pipe is intermixed with old steel pipe. The potential of bright new steel is typically more negative than that of old rusted steel, resulting in rapid corrosion of the new steel unless the new section is electrically insulated from the old section and (or) cathodically protected. A similar corrosive condition can occur if, during work on an existing piping system, tools cut or scrape the pipe and expose areas of bright steel. The potential of these bright spots will be more negative than the remainder of the pipe, resulting in accelerated corrosion in low-resistivity soils.

The relative size of anodic and cathodic areas can have a significant effect on the severity of the differential corrosion cell. In general, the severity of corrosion of the anodic areas increases as the ratio of the anodic to the cathodic area decreases. When the anode is small and the cathode is large, the anode will be subject to a high density of current discharge per unit area, with the total amount of current flowing governed by the kinetics of the oxidation and reduction reactions and the soil resistivity. The current collected per unit area on the cathode is

relatively low and may not be sufficient to result in any degree of polarization, which would tend to limit corrosion current. In a low-resistivity soil, corrosion can be rapid.

Microbiologically Influenced Corrosion

Microbiologically influenced corrosion (MIC) is defined as corrosion that is influenced by the presence and activities of microorganisms, including bacteria and fungi. It has been estimated that 20 to 30% of external corrosion on underground pipelines is MIC-related (Ref 5). Microorganisms located at the metal surface do not directly attack the metal or cause a unique form of corrosion. The by-products from the organisms promote several forms of corrosion, including pitting, crevice corrosion, and under-deposit corrosion. Typically, the products of a growing microbiological colony accelerate the corrosion process by either interacting with the corrosion products to prevent natural film-forming characteristics of the corrosion products that would inhibit further corrosion, or providing an additional reduction reaction that accelerates the corrosion process.

A variety of bacteria have been implicated in exacerbating corrosion of underground pipelines, and these fall into the broad classifications

of aerobic and anaerobic bacteria (Ref 12). Obligate aerobic bacteria can only survive in the presence of oxygen, while obligate anaerobic bacteria can only survive in its absence. A third classification is facultative aerobic bacteria that prefer aerobic conditions, but can live under anaerobic conditions. Common obligate anaerobic bacteria implicated in corrosion include sulfate-reducing bacteria (SRB) and metal-reducing bacteria. Common obligate aerobic bacteria include metal-oxidizing bacteria, while acid-producing bacteria are facultative aerobes. The most aggressive attack generally takes place in the presence of microbial communities that contain a variety of types of bacteria. In these communities, the bacteria act cooperatively to produce conditions favorable to the growth of each species. Obligate anaerobic bacteria can thrive in aerobic environments when they are present beneath biofilms/deposits in which aerobic bacteria consume the oxygen. An example is shown in Fig. 3. In the case of underground pipelines, the most aggressive attack has been associated with acid-producing bacteria in such bacterial communities (Ref 5).

Stray Current Corrosion

Corrosion of underground pipelines can be accelerated by stray dc flowing in the soil near the pipeline. Sources of direct electrical current include foreign pipelines that are not properly bonded to the pipeline and ground currents from dc sources. Electrified railroads, mining operations, and other similar industries that utilize large amounts of dc sometimes allow a significant portion of current to use a ground path return to their power sources. These currents often utilize pipelines in close proximity as a part of the return path. This "stray" current can be picked up by the pipeline and discharged back into the soil at some distance down the pipeline close to the current return. Current pickup on the pipe is the same process as cathodic protection, which tends to mitigate corrosion. The process of discharge of a dc off the pipe and through the soil accelerates corrosion of the pipe wall at the discharge point, causing stray current corrosion. The morphology of stray current corrosion tends to be very localized at holidays (defects or holes) in the pipeline coating. Rates of attack can be very high, resulting in rapid perforation of a pipeline.

In the case of stray current corrosion from a foreign pipeline, the pipeline acts as a return current path for the cathodic protection system on the foreign pipeline. Stray current corrosion occurs where the dc discharges from the pipeline and collects onto the foreign pipeline, as shown in Fig. 4. While relatively rare, cathodic protection rectifiers are occasionally connected backwards, such that dc current is discharged from the pipeline and the impressed current "anode" actually collects rather than discharges current. This can result in severe stray current corrosion of the pipeline (Fig. 5).

Fig. 3 Iron-related bacteria creating a differential oxygen and pH cell on a metal surface

Fig. 4 Stray current corrosion caused by foreign pipeline

Fig. 5 Pipeline that experienced stray current corrosion caused by inverting the electrical leads to a cathodic protection rectifier

Field experience and laboratory research results indicate that stray alternating current (ac) also can cause accelerated corrosion of underground pipelines (Ref 13). The most common sources of stray ac are induced ac from power lines and pipelines in a common right of way and ground faults from ac power transmission. It is generally agreed that ac-enhanced corrosion rates are only a small fraction (<1%) of those of dc currents. Nevertheless, corrosion damage can be extensive where the ac currents are large.

Stress-Corrosion Cracking

Stress-corrosion cracking (SCC) is defined as cracking of a material produced by the combined action of corrosion and tensile stress. There are two forms of external SCC on underground pipelines: high-pH SCC (also referred to as classical SCC) and near-neutral-pH SCC (also referred to as low-pH SCC). A characteristic of both forms of SCC is the development of colonies of longitudinal surface cracks in the body of the pipe that link up to form long, shallow flaws. In some cases, growth and interlinking of the stress-corrosion cracks produce flaws that are of sufficient size to cause leaks or ruptures of pipelines. An example of an SCC colony that caused a pipeline failure is shown in Fig. 6.

The high-pH form of SCC is intergranular (Ref 14), the cracks propagate between the grains in the metal, and there is usually little evidence of general corrosion associated with the cracking

Fig 6 Example of colony of stress-corrosion cracks on external surface of high-pressure gas transmission pipeline. The top scale is inches and the bottom is centimeters.

Fig. 7 Intergranular high-pH stress-corrosion crack in line pipe steel. Nital etchant. Original magnification: 400×

(Fig. 7). The near-neutral-pH form of SCC is transgranular—the cracks propagate through the grains in the metal—and it is associated with corrosion of the crack faces and, in some cases, with corrosion of the external surface of the pipe as well (Fig. 8). This form of cracking was first reported on a polyethylene-tape coated pipeline on the TransCanada Pipelines Ltd. (TCPL) system in the 1980s (Ref 15, 16).

Stages of SCC

Figure 9 shows a “life” model for a pipeline containing stress-corrosion cracks (Ref 17). The model consists of four stages. In stage 1, the conditions for the initiation of SCC develop at the pipe surface. The coating disbonds, a cracking electrolyte develops at the pipe surface, and the pipe surface may become pitted or modified in other ways as a result of the presence of the electrolyte. Cracks begin to initiate in stage 2, and continued initiation, growth, and crack coalescence occur in stage 3. In stage 4, large cracks coalesce and final failure occurs. The coalescence of individual stress-corrosion cracks helps to determine whether a colony of cracks is an integrity concern. If cracks nucleate in close proximity to one another, crack growth may be dominated by the coalescence of collinear cracks. Coalescence can occur throughout the SCC life cycle. Depending on the size of the crack, either environmental or mechanical forces can cause the cracks to grow during stage 3. In stage 4 of growth, coalescence may occur primarily by tearing, when mechanical loading has a stronger effect in producing crack growth.

Fig. 8 Transgranular near-neutral-pH stress-corrosion crack in Nital etchant. Original magnification: 100×

Conditions for SCC

Three conditions are necessary for SCC initiation and propagation in stages 2 and 3 to occur. These conditions generally differ for the two types of cracking:

- A potent environment develops at the pipe surface.
- The pipe steel is susceptible to SCC.
- A tensile stress of sufficient magnitude is present.

Further discussion of these three conditions for high-pH and near-neutral-pH SCC is given in this section.

Potent Environment. The two forms of external SCC are associated with two distinct environments that develop at the surface of underground pipelines. In the case of near-neutral-pH SCC, the cracking environment appears to be a dilute groundwater containing dissolved CO_2 . The source of the CO_2 is typically the decay of organic matter and geochemical reactions in the soil. This form of cracking occurs under conditions in which there is little if any CP current reaching the pipe surface, either because of the presence of a shielding coating, a high-resistivity soil, or inadequate CP design (Ref 18). In the case of high-pH SCC, CO_2 is also involved. Cathodic protection causes the pH of the electrolyte beneath disbonded coatings to increase, and the CO_2 readily dissolves in the elevated-pH electrolyte, resulting in the generation of a concentrated $\text{CO}_3\text{-HCO}_3$ electrolyte (Ref 14). Four factors determine whether either of these potent environments can develop at the pipe surface: coating, soil, CP, and temperature.

Coating. To date, one or both forms of SCC have occurred under polyethylene/polyvinyl chloride (PVC) tapes, coal-tar enamel, wax, and asphalt coatings. With these coatings, the SCC is associated with coating disbondment and shielding of the CP current by the coating. The near-neutral-pH form of SCC is most prevalent on tape-coated pipelines, while high-pH SCC has occurred most frequently on coal-tar-coated pipelines. Fusion-bonded-epoxy (FBE)-coated pipelines are very resistant to SCC. This resistance has been attributed to the grit-blasted surface preparation used with FBE coatings, which imparts a compressive residual stress, as well as the resistance of FBE coatings to disbondment and CP shielding (Ref 19–22). Other newer coatings, such as urethanes, also have these beneficial characteristics.

Soil. High-pH SCC has occurred in a wide variety of soils, covering a range in color, texture, and pH. The moisture content of the soil, the ability of the soil to cause coating damage, and localized variation in the level of CP are the primary soil-related factors affecting high-pH SCC (Ref 23). Recent research results have suggested that some minimum concentration of soluble cations in the soil, such as sodium or potassium, must be present for high-pH SCC to occur (Ref 24). This notion is not altogether surprising in that such ions must be present

Fig. 9 Life model for a colony of stress-corrosion cracks. Source: Ref 17

to maintain solubility of the carbonate and bicarbonate ions.

Near-neutral-pH SCC of tape-coated pipelines has been predominantly located in imperfectly to poorly drained soils in which anaerobic and seasonally reducing environmental conditions were present (Ref 18, 25). On asphalt-coated pipelines, near-neutral-pH SCC has been found predominantly in extremely dry terrains consisting of either sandy soils or a mixture of sand and bedrock. There was inadequate CP in these locations, based on pipe-to-soil potential measurements or pH measurements of electrolytes found beneath disbonded coatings (Ref 17).

Cathodic protection is closely related to the high-pH cracking process. The CP current collecting on the pipe surface at disbondments, in conjunction with dissolved CO_2 in the groundwater, generates the high-pH SCC environment. Cathodic protection can also place the pipe-to-soil potential in the potential range for cracking. The potential range for cracking generally lies between the native potential of underground pipelines and the potential associated with adequate protection (-850 mV copper/copper sulfate electrode, or CSE) (Ref 26–28). Because the rate of generation of the cracking environment is related to the CP current, it is likely that seasonal fluctuations in the CP system are associated with the cracking process. The potent cracking environment might be generated during portions of the year when CP levels are high, while cracking might occur when adequate protection is lost, such as in the summer months when the soil dries out.

It has been concluded from the results of extensive field investigations (Ref 18, 25) that near-neutral-pH SCC occurs in the absence of significant CP. At dig sites on tape-coated pipelines, where near-neutral-pH SCC is found, the cracking is associated with locations where CP current was shielded from the pipe surface, based on pH measurements of electrolytes. The lower

occurrence of SCC on the asphalt-coated portions of the system probably can be attributed to the higher levels of CP associated with this type of coating.

Temperature. The incidence of high-pH SCC increases significantly with an increase in the operating temperature of a pipeline. Service failures have been reported at temperatures as low as 13°C (55°F), but 90% of the service and hydrostatic test failures have occurred within 16 km (10 miles) downstream from compressor stations (Ref 27). This behavior has been attributed to a decrease in the width of the potential range for cracking, as shown in Fig. 10, coupled with a decrease in the maximum cracking velocity with decreasing temperature. Laboratory data and field experience indicate that there is less temperature dependence for near-neutral-pH SCC than for high-pH SCC.

Susceptible Line Pipe Steel. Both forms of SCC have occurred on a variety of sizes, grades, and vintages of line pipe steel. Stress-corrosion cracking has been found in flash welded, submerged arc welded (SAW), electric resistance welded (ERW), and seamless pipe. The chemical compositions of the failed pipes are typical for the vintage and grade, and there are no obvious unique metallurgical characteristics associated with the failures. The bond line of the weld seam of ERW pipe seems to have a lower resistance to near-neutral-pH SCC than the base metal, possibly because of the presence of a more SCC-susceptible microstructure at the weld, a higher-than-normal residual stress, pits and arc burns associated with the ERW manufacturing process, or a lower fracture toughness (Ref 17). The coarse-grained heat-affected zone (CGHAZ) adjacent to the double submerged arc weld (DSAW) also has been found to be more susceptible to cracking than the base material in the near-neutral-pH environment (Ref 29). Results of recent research suggest that residual stresses from the pipe manufacturing process are

important in affecting susceptibility to near-neutral-pH SCC (Ref 30).

Tensile Stress. Most of the intergranular (high-pH) stress-corrosion cracks found in gas transmission pipelines have been oriented in the longitudinal direction (Ref 14). This orientation indicates the importance of the hoop stress produced by the internal pressurization on the cracking process. The failures have occurred at hoop stresses ranging from 160 to 270 MPa (23 to 39 ksi), which corresponded to 46 to 76% of the specified minimum yield strength (SMYS) of the pipe steels. Most of the high-pH SCC failures have initiated at locations at which there was no indication of secondary stresses. These observations indicate that the typical field stresses experienced by operating gas transmission pipelines are sufficient for high-pH SCC to occur.

The majority of near-neutral-pH SCC failures are associated with features that enhance the local stress, indicating that the behavior is fundamentally different from high-pH SCC with regard to the role of stress in the crack initiation process. In most cases, near-neutral pH SCC has been associated with corrosion, gouges, or stress concentrations from the toe of the weld seam that raise the local stress above the hoop-stress levels calculated based on the internal pressurization (Ref 17). Significant SCC has not been reported in class 2 and 3* pipeline locations, indicating that the hoop stress also is important (Ref 17).

Cyclic pressure fluctuations that normally occur on operating pipelines also affect SCC behavior. It has been demonstrated that the cyclic stress that results from these pressure

*Class locations for high-pressure gas pipelines are defined by the U.S. Department of Transportation based on the consequences of a pipeline failure. Class 1 locations have the lowest consequence and are allowed to operate at a maximum pressure that is equivalent to 72% of SMYS. Class 4 locations have the highest consequence of failure and are allowed to operate at a maximum pressure that is equivalent to 40% of SMYS (Reference CFR Part 192.111).

fluctuations reduce the threshold stress for initiation of high-pH SCC (Ref 31) and increase the rate of propagation of near-neutral-pH stress-corrosion cracks (Ref 32).

Prevention and Mitigation of Corrosion and SCC

The most effective method to prevent corrosion or SCC on new pipelines is to use high-performance coatings, applied to a surface abrasive blast cleaned to a white (Ref 33) or near-white (Ref 34) metal surface finish, in conjunction with effective CP. An intact coating that prevents contact of electrolyte with the steel surface will prevent external corrosion or SCC. The surface abrasive blast cleaning promotes good coating adhesion. A high-quality abrasive blast cleaning also will impart compressive residual stresses in the pipe surface that improve SCC resistance.

All coatings contain some defects or holes, referred to as holidays, that expose the bare pipeline steel to the underground environment. The function of the CP system is to protect these bare areas from corrosion.

Methods of preventing corrosion and SCC on existing pipelines include minimizing the operating temperature and controlling the CP levels to values more negative than -850 mV CSE. Minimizing pressure fluctuations on operating pipelines also is effective in preventing SCC initiation. A more detailed discussion of coatings and cathodic protection is given in this section.

Coatings

Inadequate coating performance is a major contributing factor in the corrosion and SCC susceptibility of an underground pipeline. The function and desired characteristics of a dielectric-type pipeline coating are covered in NACE RP-0169 (Ref 35). This specification states that the function of such coatings is to control corrosion by isolating the external surface of the underground or submerged piping from the environment, to reduce CP requirements, and to improve (protective) current distribution. Coatings must be properly selected and applied, and the coated piping must be carefully installed to fulfill these functions. The desired characteristics of the coatings include:

- Effective electrical insulation
- Effective moisture barrier
- Good adhesion to the pipe surface
- Applicable by a method that will not adversely affect the properties of the pipe
- Applicable with a minimum of defects
- Ability to resist the development of holidays with time
- Ability to resist damage during handling, storage, and installation
- Ability to maintain substantially constant resistivity with time

- Resistance to disbonding
- Resistance to chemical degradation
- Ease of repair
- Retention of physical characteristics
- Nontoxic to environment
- Resistance to changes and deterioration during above-ground storage and long-distance transportation

Descriptions of common coatings used on underground pipelines follow.

Bituminous enamels are formulated from coal-tar pitches or petroleum asphalts and have been widely used as protective coatings for more than 65 years. Coal-tar and asphalt enamels are available in summer or winter grades. These enamels are the corrosion coating; they are combined with various combinations of fiberglass and/or felt to obtain mechanical strength for handling. The enamel coatings have been the workhorse coatings of the industry, and when properly selected and applied, they can provide efficient long-term corrosion protection.

Enamel systems can be designed for installation and use within an operating temperature range of -1 to 82 °C (30 to 180 °F). When temperatures fall below 4.4 °C (40 °F), added precautions should be taken to prevent cracking and disbonding of the coating during field installation. Enamels are affected by ultraviolet rays and should be protected by kraft paper or whitewash. Enamels are also affected by hydrocarbons, and the use of a barrier coat is recommended when known contamination exists. Bituminous enamel coatings are available for all sizes of pipe.

In recent years, the use of enamels has declined for these reasons:

- Reduced number of suppliers
- Restrictive environmental and health standards from the Occupational Safety and Health Administration, the Environmental Protection Agency, and the Food and Drug Administration
- Increased acceptance of other coating types
- Alternative use of coating raw materials as fuels

Asphalt mastic pipe coating is a dense mixture of sand, crushed limestone, and fiber bound together with a select air-blown asphalt. These materials are proportioned to secure a maximum density of approximately 2.1 g/cm³ (132 lb/ft³). This mastic material is available with various types of asphalt. Selection is based on operating temperature and climatic conditions to obtain maximum flexibility and operating characteristics. This coating is a thick (12.7 to 16 mm, or $1/2$ to $5/8$ in.) extruded mastic that results in a seamless corrosion coating. Extruded asphalt mastic pipe coating has been in use for more than 50 years.

Asphalt mastic systems can be designed for installation and use within an operating range of 4.4 to 88 °C (40 to 190 °F). Precautionary measures should be taken when handling asphalt mastics in freezing temperatures. Whitewash is

used to protect it from ultraviolet rays, and this should be maintained when in storage. This system is not intended for use above ground or in hydrocarbon-contaminated soils.

Liquid Epoxies and Phenolics. Many different liquid systems are available that cure by heat and/or chemical reaction. Some are solvent types, and others are 100% solids. These systems are primarily used on larger-diameter pipe when conventional systems may not be available or when they may offer better resistance to operation temperatures in the 95 °C (200 °F) range.

Generally, epoxies have an amine or a polyamide curing agent and require a near-white blast-cleaned surface (NACE No. 2 or SSPC SP10). Coal-tar epoxies have coal-tar pitch added to the epoxy resin. A coal-tar epoxy cured with a low-molecular-weight amine is especially resistant to an alkaline environment, such as that which occurs on a cathodically protected structure. Some coal-tar epoxies become brittle when exposed to sunlight.

Extruded plastic coatings fall into two categories based on the method of extrusion, with additional variations resulting from the selection of adhesive. The two methods of extrusion are the crosshead or circular die, and the side extrusion or T-shaped die. The four types of adhesives are asphalt-rubber blend, polyethylene copolymer, butyl rubber adhesive, and polyolefin rubber blend.

To date, of the polyolefins available, polyethylene has found the widest use, with polypropylene being used on a limited basis for its higher operating temperature. Each type or variation of adhesive and method of extrusion offers different characteristics based on the degree of importance to the user of certain measurable properties.

Fusion-bonded epoxy (FBE) coatings are heat-activated, chemically cured coating systems. The epoxy coating is furnished in powdered form and, with the exception of the welded field joints, is plant applied to preheated pipe, special sections, connections, and fittings using fluid-bed, air spray, or electrostatic spray methods.

Fusion-bonded epoxy coatings were introduced in 1959 and were first used as an exterior pipe coating in 1961 and currently are the coatings most commonly used for new installations of large diameter pipelines (Ref 36). These coatings are applied to preheated pipe surfaces at 218 to 244 °C (425 to 475 °F). Some systems may require a primer system, and some require postheating for complete cure. A NACE No. 2 (SSPC SP10) near-white blast-cleaned surface is required. The coating is applied to a minimum thickness of 0.3 mm (12 mils); in some applications, coating thicknesses range to 0.64 mm (25 mils), with the restriction not to bend pipe coated with a film thickness greater than 0.4 mm (16 mils). The FBE coatings exhibit good mechanical and physical properties and are the most resistant to hydrocarbons, acids, and alkalis.

A primary advantage of the FBE pipe coatings is that they cannot hide apparent surface defects; therefore, the steel surface can be inspected after it is coated. The number of holidays that occur is a function of the surface condition and the thickness of the coating specified. Increasing the thickness minimizes this problem, and the excellent resistance to the electrically induced disbondment of these coatings has resulted in their frequent use as pipeline coatings.

Tape. Field and mill-applied tape systems have been in use for more than 30 years on pipelines. For normal construction conditions, prefabricated cold-applied tapes are applied as a three-layer system consisting of a primer, corrosion-preventive tape (inner layer), and a mechanically protective tape (outer layer). The function of the primer is to provide a bonding medium between the pipe surface and the adhesive or sealant on the inner layer. The inner-layer tape consists of a plastic backing and an adhesive. This layer is the corrosion-protective coating; therefore, it must provide a high electrical resistivity, low moisture absorption and permeability, and an effective bond to the primed steel surface. The outer-layer tape consists of a plastic film and an adhesive composed of the same types of materials used in the inner tape or materials that are compatible with the inner-layer tape. The purpose of the outer-layer tape is to provide mechanical protection to the inner-layer tape and to be resistant to the elements during outdoor storage. The outer-layer tape is usually a minimum of 0.64 mm (25 mils) thick.

The cold-applied multilayer tape systems are designed for plant coating operations and result in a uniform, reproducible, holiday-free coating over the entire length of any size pipe. The multiple-layer system allows the coating thickness to be custom designed to meet specific environmental conditions. These systems have been engineered to withstand normal handling, outdoor weathering, storage, and shipping conditions.

Three-Layer Polyolefin. The three-layer polyolefin pipeline coating was developed in the 1990s as a way to combine the excellent adhesion of FBE with the damage resistance of extruded polyethylene and tape wraps. These systems consist of an FBE primer, an intermediate copolymer layer, and a topcoat consisting of either polyethylene or polypropylene. The function of the intermediate copolymer is to bond the FBE primer with the polyolefin topcoat.

Variations in these three-layer systems exist, most notably the use of either polyethylene or polypropylene for the topcoat. Polypropylene offers a higher temperature resistance but is more costly, both as a raw material and because higher temperatures are required for application. Most topcoats are side extruded similar to extruded polyethylene coatings, although at least one product uses flame-spray polyolefin for a topcoat. Another variation in the three-layer systems is the thickness of the FBE primer layer. Early generations of this product utilized a

50–75 μm (2–3 mil) primer which often proved to be inadequate to achieve the desired performance. More recent three-layer systems utilize a 200–300 μm (8–12 mil) primer as a standard thickness.

Wax coatings have been in use for more than 50 years and are still employed on a limited basis. Microcrystalline wax coatings are usually used with a protective overwrap. The wax serves to waterproof the pipe, and the wrapper protects the wax coating from contact with the soil and affords some mechanical protection. The most prevalent use of wax coatings is the over-the-ditch application with a combination machine that cleans, coats, wraps, and lowers into the ditch in one operation.

Special-Use Coatings

Polyurethane Thermal Insulation. Efficient pipeline insulation has grown increasingly important as a means of operating hot and cold service pipelines. This is a system for controlling heat transfer in above- or belowground and marine pipelines. Polyurethane insulation is generally used in conjunction with a corrosion coating, but if the proper moisture vapor barrier is used over the polyurethane foam, effective corrosion protection is attained.

Concrete. Mortar linings and coatings have the longest history of use in protecting steel or wrought iron from corrosion. The alkalinity of the concrete promotes the formation of a protective iron oxide (passive) film on the steel. This protective passive film can be compromised in underground applications by permeation of chlorides into the coating. Typically, external application is usually employed over a corrosion-resistant coating for armor protection and negative buoyancy in marine environments.

Metallic (Galvanic) Coatings. Pipe coated with a galvanic coating, such as zinc (galvanizing) or cadmium, should not be utilized in direct burial service. Such metallic coatings are intended for the mitigation of atmospheric-type corrosion activity on the substrate steel.

Evaluating Coatings

As described previously, the different types of coatings used on underground pipelines have different strengths and weaknesses. When first installed, most pipeline coatings are effective in meeting their required function: isolate the external surface of an underground pipeline from the environment, reduce the CP current requirements, and improve the CP current distribution. On the other hand, coatings vary significantly in their long-term performance. Ultimately, the effectiveness of a coating system in preventing corrosion is related to two primary factors: (a) the resistance of a coating to degradation over time and (b) the ability of the coating to conduct CP current should the coating fail (minimize shielding). For SCC resistance, these factors as

well as the type of surface preparation used with the coating are important.

The ability of a coating to resist degradation is a primary performance property of coatings and affects all forms of external pipeline corrosion. The second factor, the ability of a coating to pass CP current, should it fail, is the inverse of shielding of the CP current beneath a disbonded coating. Corrosion or SCC can occur beneath a disbonded coating that shields CP current even though the pipeline is apparently effectively protected, based on ground-level measurements.

Surface Preparation

The nature of the surface preparation is probably more important in mitigating SCC than other forms of corrosion. Historically, the primary purposes of the surface preparation have been to clean the surface and create an anchor pattern to promote good adhesion of the coating to the pipe surface. The surface preparation requirements for different coating types vary. For example, bituminous coatings have good adhesion properties on commercial blast-cleaned surfaces (NACE No. 3/SSPC-SP 6) or even on wire-brushed surfaces, whereas fusion-bonded epoxy (FBE) coatings require a white (NACE No. 1/SSPC-SP 5) or near-white (NACE No. 2/SSPC-SP 10) grit-blasted surface finish for proper adhesion. Laboratory research and field experience have demonstrated that grit-blasted surfaces are generally more resistant to SCC initiation than wire-brushed mill-scaled surfaces, primarily because grit blasting imparts a compressive residual stress in the pipe surface (Ref 20, 21, 36). A white or near-white surface finish was found to be required to impart SCC resistance, whereas commercially blasted surfaces were found to be more susceptible to SCC than wire-brushed milled scaled surfaces.

The Canadian Energy Pipeline Association (CEPA) member companies have recommended that the following coatings be considered for new construction based on SCC performance (Ref 37):

- Fusion-bonded epoxy
- Liquid epoxy
- Urethane
- Extruded polyethylene
- Multilayer or composite coatings

Fusion-bonded epoxies, liquid epoxies, and urethane coatings meet all three requirements of an effective coating: (a) they are resistant to degradation over time, (b) they conduct CP current should they fail, and (c) they are typically applied over a white or near-white grit-blasted surface. Extruded polyethylene coatings meet requirements 1 and 3, but will shield CP current should disbondment occur. Furthermore, the type of coating used on the field joints frequently limits the performance of extruded polyethylene-coated pipelines. Multilayer or composite coatings typically consist of an FBE inner layer and a polyolefin outer layer with an adhesive between

the two layers. These new coatings are promising from the standpoint of resistance to disbondment, mechanical damage, and soil stresses, but the polyolefin outer layer will shield CP current should disbondment occur. Additional field experience is needed to establish the performance of these coatings.

Tape coatings and bituminous coatings have been shown to be more susceptible to SCC than the aforementioned coatings and should be used only with careful consideration of all of the factors affecting SCC. Regardless of the coating selected, the pipe surface should be prepared to a white (NACE No. 1/SSPC-SP 5) or near-white (NACE No. 2/SSPC-SP 10) finish to aid in coating adhesion and impart sufficient residual compressive stresses to prevent SCC initiation. A lower-quality commercial blast (NACE No. 3/SSPC-SP 6) should not be used under any circumstances.

Cathodic Protection

External corrosion and SCC are electrochemical phenomena and, therefore, can be prevented or mitigated by altering the electrochemical condition of the corroding interface. Altering the electrochemical nature of the corroding surface is relatively simple and is done by altering the electrical potential field around the pipe. By applying a negative potential and making the pipe a cathode, the rate of corrosion (oxidation) is reduced (corrosion is prevented or mitigated) and the reduction process is accelerated. This means of mitigating (or preventing) corrosion, cathodic protection, also alters the environment at the pipe surface, which further enhances corrosion control. The pH of any electrolyte at the pipe surface is increased, the oxygen concentration is reduced, and deleterious anions, such as chloride, migrate away from the pipe surface.

Types of CP. There are two primary types of CP systems: sacrificial anode (galvanic anode) CP and impressed-current CP. Sacrificial anode CP utilizes an anode material that is electro-

negative to the pipe steel. When connected to the pipe, the pipe becomes the cathode in the circuit and corrosion is mitigated. Typical sacrificial anode materials for underground pipelines are zinc and magnesium. Impressed-current CP utilizes an outside power supply (rectifier) to control the voltage between the pipe and an anode (cast iron, graphite, platinum clad, mixed metal oxide, etc.) in such a manner that the pipe becomes the cathode in the circuit and corrosion is mitigated. Schematics of these two types of CP systems are shown in Fig. 11 and 12.

Cathodic protection is most often used in conjunction with a coating. There are always flaws in the coating due to application inconsistencies, construction damage, or the combination of natural aging and soil stresses. If left unprotected, the pipeline will undergo corrosion or SCC at these coating flaws (holidays). Often the rate of attack through the wall is much higher at the holiday than the general attack of a bare steel surface. The use of a coating greatly reduces the total amount of current required to achieve protection of the pipeline system; therefore, CP and external coatings are utilized together wherever possible.

Cathodic protection can be used to control all types of corrosion previously discussed (general, stray current, MIC, and SCC). Sometimes it is difficult to determine the level of CP necessary to mitigate the different corrosion mechanisms and to identify which type of corrosion is present. Stress-corrosion cracking presents additional problems. First, the high-pH form of SCC is only found on pipelines protected with CP. The products that result from cathodic reactions occurring on the pipe surface during CP in conjunction with soil chemistry produce the environment necessary for high-pH SCC. Since high-pH SCC propagates only in a very limited potential range, maintaining the potential of the pipe surface outside of this range by proper CP control will prevent growth of the high-pH SCC cracks. In addition, it has been established that proper CP control can inhibit the growth of near-neutral SCC cracks.

Electrical surveys have been performed to evaluate the level of CP ever since the application of CP to pipelines in the 1940s. These surveys consist of measuring the potential (pipe-to-soil potential) of the pipe surface with respect to a reference electrode (typically CSE). These measurements can be performed at permanent test station locations (test point surveys), or they can be performed continuously with a 1 to 2 m (3 to 6 ft) spacing along the entire length of the pipeline (close interval surveys). Pipe-to-soil potential surveys can be performed with the CP system energized (on-potentials) or with the CP system interrupted (off-potentials). There has been much discussion over the past 10 to 20 years as to the most appropriate survey methodology. While each method has its benefits, it is commonly accepted that the IR-voltage (voltage drop due to current, I , through a resistance, R) correction made by the off-potential measurement is most closely related to the corrosion condition of the pipeline. Figure 13 shows a schematic of a pipe-to-soil potential measurement.

The basic pipe-to-soil potential measurement techniques are applied to establish whether one or more of the recommended CP criteria are met. Criteria for establishing the effectiveness of a CP system to mitigate corrosion are outlined in the NACE International Recommended Practice RP0169-96 (Ref 35) and have been adopted, in part, in U.S. Department of Transportation (DOT) regulations CFR 49, Parts 192 and 195. In general, if one or more of the recommended criteria are met, the CP system is assumed to be applying a sufficient cathodic current to mitigate corrosion.

Certain pipeline conditions make conventional electrical survey techniques difficult to interpret. These include areas of stray or telluric currents, congested areas where multiple pipelines and other utilities share rights-of-way, and pipelines with noninterruptible sacrificial CP systems. In these areas, either significant care must be taken to interpret conventional surveys or other methods of monitoring must be utilized. One such technology is the use of coupon test

Fig. 11 Sacrificial anode CP system with distributed magnesium anodes and an above-ground test station

Fig. 12 Impressed current CP system with above-ground rectifier and a single remote anode groundbed

stations. The coupon test stations permit accurate potential measurements for a test specimen (coupon) that simulates a holiday on the pipe surface.

Detection of Corrosion and SCC

On existing pipelines, there are three methods to detect corrosion and SCC—hydrostatic retesting, field investigation programs (direct assessment), and in-line inspection.

Hydrostatic Testing. Hydrostatic retesting involves pressure testing the pipeline with water at a pressure that is higher than the operating pressure, typically 125% of the maximum operating pressure (MOP) of the pipeline. This is the most common method to ensure the integrity of a pipeline and establish a safe operating pressure, regardless of the types of flaws present in the pipeline. Any flaws that are larger than a critical size at the hydrostatic retest pressure are removed from the pipeline. However, subcritical flaws remain in the pipeline after a hydrostatic retest. If the defects are growing with time, as might be the case with corrosion or SCC, the pipeline is generally periodically retested to ensure integrity. Hydrostatic retesting is expensive and creates problems associated with the acquisition, treatment, and disposal of the water, especially for pipelines carrying liquid products.

Direct Assessment. As a part of condition-monitoring programs, pipeline companies commonly use field investigation (direct assessment) programs. The overall condition of the coatings and pipelines is assessed, and it is determined whether corrosion or SCC is present on the system. Models are sometimes developed to predict the likelihood of the presence and severity of corrosion or cracking. This information is then used to prioritize the system for direct examination, hydrostatic testing, in-line inspection, recoating, or pipe replacement. Dig programs and the associated models are not generally considered as a replacement for hydrostatic testing as a means to ensure the integrity of a pipeline. See the article “External Corrosion Direct Assessment Integrated with Integrity Management” in this Volume.

Fig. 13 Pipe-to-soil potential measurement

In-line inspection (ILI) tools, also referred to as smart or intelligent pigs, are devices that are propelled by the product in the pipeline and are used to detect and characterize metal loss caused by corrosion and cracking. There are two primary types of metal-loss ILI tools: magnetic flux leakage (MFL) tools and ultrasonic tools (UT).

Magnetic flux leakage tools measure the change in magnetic flux lines produced by the defect and produce a signal that can be correlated to the length and depth of a defect. In recent years, the magnetics, data storage, and signal interpretation have improved, resulting in improved mapping of the flaw and a decrease in the number of unnecessary excavations. The high-resolution MFL tool is typically capable of readily detecting corrosion pits with a diameter greater than three times the wall thickness. Once detected, these tools can typically size the depth of the corrosion within $\pm 10\%$ of the wall thickness with an 80% level of confidence. The MFL tool can be used to inspect either liquid product pipelines or natural gas pipelines.

Figure 14 shows a typical MFL tool. The wire brushes in the front of the tool are used to transfer the magnetic field from the tool to the pipe wall. The ring of sensors between the wire brushes are used to measure the flux leakage produced by defects in the pipe. The drive cups are the mechanism that is used to propel the tool by the product in the pipeline. The odometer wheels monitor the distance traveled in the line and are used to determine the location of the defects identified. The trailing set of inside-diameter/outside-diameter sensors (ID/OD sensors) is used to discriminate between internal and external wall loss.

Ultrasonic tools utilize large arrays of ultrasonic transducers to send and receive sound waves that travel through the wall thickness, permitting a detailed mapping of the pipe wall. Ultrasonic tools can indicate whether the wall

loss is internal or external. The typical resolution of a UT is $\pm 10\%$ of the pipe wall thickness with an 80% level of confidence. Ultrasonic tools are typically used in product pipelines (those carrying crude oil, gasoline, and the like) since the product in the pipeline is used as the required couplant for the ultrasonic sensors. This tool can be used to inspect natural gas pipelines, but requires introducing a liquid (such as water) into the pipeline for an ultrasonic couplant.

There is significant interest in the pipeline industry in developing ILI tools that can reliably detect and size stress-corrosion cracks. Crack-detection tools avoid problems associated with acquisition, treatment, and disposal of the water used in hydrostatic retesting. It is desirable for a fully developed tool to be capable of detecting and sizing subcritical cracks such that the pipeline can be repaired long before these cracks become an integrity concern. The detection of smaller cracks also extends the time interval between inspections. Ultrasonic tools are available that can detect stress-corrosion cracks in liquid pipelines, but the detection and sizing capability of the tools has not been fully established. These tools require the presence of a liquid couplant and therefore are difficult and expensive to use in gas pipelines.

Assessment and Repair of Corrosion and SCC

Once corrosion or SCC has been detected on a pipeline, the size of the defect must be determined, and the defect must then be assessed and sentenced. In-line inspection typically provides some measure of the size of the defect. The dimensions of ILI defects that potentially could affect the immediate integrity of the pipeline are typically confirmed by direct examination. In direct assessment (DA) programs, corrosion

Fig. 14 Magnetic flux leakage tool for detection and sizing of corrosion defects in a pipeline. Courtesy of PII

flaws can be sized by direct measurement or by means of an ultrasonic thickness meter. Stress-corrosion cracks are generally sized, in the field, by a combination of magnetic-particle inspection (MPI) and grinding. The colony with the longest interlinked cracks in a dig is typically ground out to establish the maximum depth of cracking. In the ditch ultrasonic techniques also are being developed for crack dimension measurements, but the technology is difficult to apply to colonies of cracks.

A burst-pressure model such as R-STRENG (Ref 38) can be used to determine the failure pressure of corrosion defects or areas that contained cracks and were subsequently ground out. Fracture mechanics techniques must be used to determine the burst pressure of cracklike defects (Ref 17). The pipe is typically recoated if the burst pressure is within acceptable limits (typically above a pressure that is equivalent to 100% of the specified minimum yield strength of the line pipe steel). If this pressure is below acceptable limits, the pipe is typically replaced or repaired using a steel or composite reinforcing sleeve and recoated.

Pipe replacement is sometimes the only option in situations in which there is extensive corrosion or cracking localized within one area of a pipeline. If the corrosion or cracking is extensive, but not severe, it may be possible to recoat the affected areas of a pipeline. Enhancement of the CP system is also an option to minimize further corrosion or stress-corrosion crack growth in areas in which it has been established that the pipeline contains growing corrosion or SCC defects that are not an immediate integrity threat. Unfortunately, shielding coatings are not amenable to enhancement of CP because it is unlikely that the CP current can penetrate beneath coating disbondments. In the case of hydrostatic retest failures, the only available repair method is pipe replacement. The failed joint is cut out and replaced with new pipe.

Natural Gas Internal Pipeline Corrosion

Sridhar Srinivasan and Dawn C. Eden, Honeywell Process Solutions, Honeywell International, Inc.

INTERNAL CORROSION IN PIPELINES is a significant problem in oil and gas transmission systems. Oil or mixed-phase transmission systems, due to the presence of an inhibiting oil phase, typically tend to be less corrosive than corresponding natural gas transmission systems that carry water vapor in the gas phase. Under normal operating conditions, gas transmission pipelines carry undersaturated gas processed by upstream dehydrating units. These pipelines are generally operated with no protection or inhibition and rely on the performance of the dehydrating units to process dry gas within acceptable standards. It is not unusual to find, in such pipelines, phase instabilities and other process perturbations resulting in near-saturated gas (with water vapor) or some liquid water carry-over. These upsets lead to water accumulation in some parts of the pipeline downstream of the separators and can cause water condensation due to pressure and temperature changes along the length of the pipeline.

Corrosion severely affects pipeline operations, leading to lost production, unscheduled downtime for maintenance or repair, and even catastrophic failure that impacts health, environment, and safety. Operators implement corrosion control measures to prevent such damage, including use of corrosion-inhibitor treatments; however, performance data are rarely available to help optimize the dosing level or the type of chemical used. Typically, pipeline systems are treated for management of general corrosion, although most failures actually result from localized (pitting) corrosion.

Corrosion measurement and assessment in unpiggable pipelines presently relies on internal corrosion direct assessment (ICDA) methods, a practice that uses proven tools but requires validating experience. As a result, approaches to corrosion measurement are often after-the-fact and rely on detection tools to show the existence of defects and damage to a pipeline. A more proactive approach can be taken by implementing on-line, real-time corrosion monitoring as a complementary tool to ICDA, where the two techniques can each provide information to assist in the optimal application of the other. In brief:

- The ICDA modeling software tools encapsulate flow and corrosion modeling function-

ality to identify where corrosion can occur, and these are fine-tuned based on real corrosion measurement data from the pipeline environment itself.

- On-line, real-time corrosion-monitoring sensors and measurement devices at strategic points identified through ICDA will, in turn, offer a quick response to upset conditions inside the pipeline. Strategic locations are most efficiently identified through an initial ICDA study.
- On-line, real-time corrosion monitoring data coupled with key pipeline process and environment data can assist the pipeline operator in understanding how corrosion changes with time and variation in pipeline operations.
- The amount of liquid water condensing, and the flow parameters, such as gas velocity, system flow regime, pipeline inclination, and other factors, determine whether water accumulates in a particular part of the pipeline. The length of time for which these upsets last influences the amount of stagnant liquid water and potentially can manifest as multiphase corroding environments. Such zones in a pipeline system, which are the first to experience water accumulation, are most susceptible to internal corrosion.
- Identifying and inspecting such critical zones reduces the effort in inspecting entire pipeline segments for internal corrosion and forms the basis for ICDA.

This article examines methods of internal corrosion prediction for multiphase pipelines (primarily gas pipelines that become corrosive because of the occurrence of condensing water phase) and details methodologies to perform ICDA for pipelines. Further, real-time monitoring techniques for assessing actual corrosion at critical locations are also discussed.

Background to Internal Corrosion Prediction

Carbon dioxide (CO₂)-based corrosion has been one of the most active areas of research in the domain of corrosion, with several predictive models for carbon steel corrosion assessment. These efforts range from a predictive model that

begins with CO₂ corrosion (Ref 1, 2), to models that focus on specific aspects of the corrosion phenomena (such as flow-induced corrosion or erosion-corrosion) (Ref 3, 4), to models that empirically relate corrosion rates to gas production and water production rates (Ref 5). In Ref 6, the physical chemistry of the corrosive medium is used as the key notion, and ionic strength, pH, and specific ionic species are taken into account as relevant factors. Other relevant efforts include the influence of hydrogen sulfide (H₂S) and O₂ on CO₂-based corrosion (Ref 7, 8).

Recent models, including one discussed in Ref 9, attempt to integrate lab data and field experience within the framework of relevant controlling parameters most prominent in oil and gas production. While there have been several studies focusing on the exact mechanism of metal dissolution in CO₂-containing waters, a commonly accepted explanation is that anodic dissolution of iron is a pH-dependent mechanism, and the cathodic process is driven by the direct reduction of undissociated carbonic acid (H₂CO₃) (Ref 2, 3, and 7). These reactions can be represented as (Ref 3):

The overall corrosion reaction can be represented as:

The buildup of the bicarbonate ion can lead to an increase in the pH of the solution until conditions promoting precipitation of iron carbonate (FeCO₃) are reached, leading to the reaction:

Iron carbonate solubility, which decreases with increasing temperature, and the consequent precipitation of iron carbonate, is a significant factor in assessing corrosivity. The charge-transfer controlled reaction involving carbonic acid and carbon steel (or iron) can be represented in terms of the concentration or partial pressure of dissolved CO₂ in the medium to arrive at a corrosion rate equation that incorporates the

order of the reaction and an exponential function that approximates for the temperature dependence of the reaction constant. This corrosion rate equation is given as (Ref 2):

$$\log(V_{\text{cor}}) = 5.8 - 1710/T + 0.67 \log(p_{\text{CO}_2}) \quad (\text{Eq 5})$$

where V_{cor} is the corrosion rate in mm/yr, T is the operating temperature in Kelvin, and p_{CO_2} is the partial pressure of CO_2 in bar.

The corrosion rate obtained by Eq 5 has typically been seen as the maximum possible corrosion rate without accounting for iron carbonate

scaling. A nomogram representing Eq 5 is given in Fig. 1 (Ref 2), which also includes a scale factor to account for the formation of protective carbonate films that lead to a reduced corrosion rate at higher temperatures.

The correlation given in Eq 5 describes CO_2 -based corrosion. There have been other significant development efforts to demonstrate effects of other environmental variables, such as pH, H_2S , chlorides, bicarbonates, water/gas/oil ratios, velocity, and so on. Effects of H_2S on corrosion rates in the laboratory have been studied and presented in Ref 7 and 10. In Ref 7, the authors indicate that the preferential formation of an iron sulfide film can decelerate the corrosion rate, especially at temperatures above 20 °C (68 °F) and extending up to 60 °C (140 °F). Above 150 °C (300 °F), the corrosion reaction falls back to the standard CO_2 -based corrosion, with an FeCO_3 film that is more stable than the FeS film. Even small amounts of H_2S can provide instantaneous protection at temperatures in the range of 70 to 80 °C (160 to 175 °F) (Ref 7).

The role of the hydrocarbon condensate in providing corrosion mitigation in specific production systems has been reviewed in Ref 11. The role of the type of oil or gas condensate is important from the standpoint of accurate assessment (Ref 12, 13). Other studies (Ref 14, 15) have evaluated the effects of critical para-

meters such as pH and velocity on CO_2 corrosion. Predictive models, including a combination of the parameters discussed in this article along with electrochemical considerations, have also been used to arrive at the corrosion rate (Ref 16, 17).

A typical flow chart delineating the hierarchical reasoning structure of a predictive model described in this article is given in Fig. 2 (Ref 9). The first step in corrosivity determination is computation of the system pH, because it is the hydrogen ion concentration that drives the anodic dissolution. Further, the role of pH in promoting or mitigating CO_2 -based corrosion has been extensively chronicled (Ref 18–21). For oil/gas production environments, where it is the dissolved CO_2 or H_2S that contributes significantly to an acidic pH, the pH can be determined as a function of acid gas partial pressures, bicarbonates, and temperature, as shown in Fig. 3 (Ref 22). From a practical standpoint, the contribution of H_2S , HCO_3^- , or temperature to pH determination is another way of representing effective levels of CO_2 that would have produced a given level of pH.

While it has been documented that the CO_2 corrosion mechanism is dissimilar to that of strong acids such as hydrochloric (HCl) acid (CO_2 corrosion is now understood to progress through direct reduction of H_2CO_3 to HCO_3^- rather than reduction of H^+ ions), and that carbonic acid corrosion is much more corrosive than that obtained from a strong acid such as HCl at the same pH (Ref 18), there is also significant agreement that lower pH levels obtained from higher acid gas presence lead to higher corrosion rates. Conversely, higher levels of pH obtained through buffering in simulated production formation water solutions have been shown to produce significantly lower corrosion rates, even at higher levels of CO_2 and/or H_2S (Ref 23). Data about the effects of pH from another study are shown in Fig. 4 (Ref 13). Hence, it is more meaningful to determine the effective CO_2 partial pressure from the system pH. Data in Fig. 3 can be represented as equations for straight lines in terms of pH and acid gas partial pressures for a given level of HCO_3^- and temperature. A numerical model can also be developed to compute pH for different values of HCO_3^- and

Fig. 1 CO_2 corrosion nomogram. Source: Ref 2

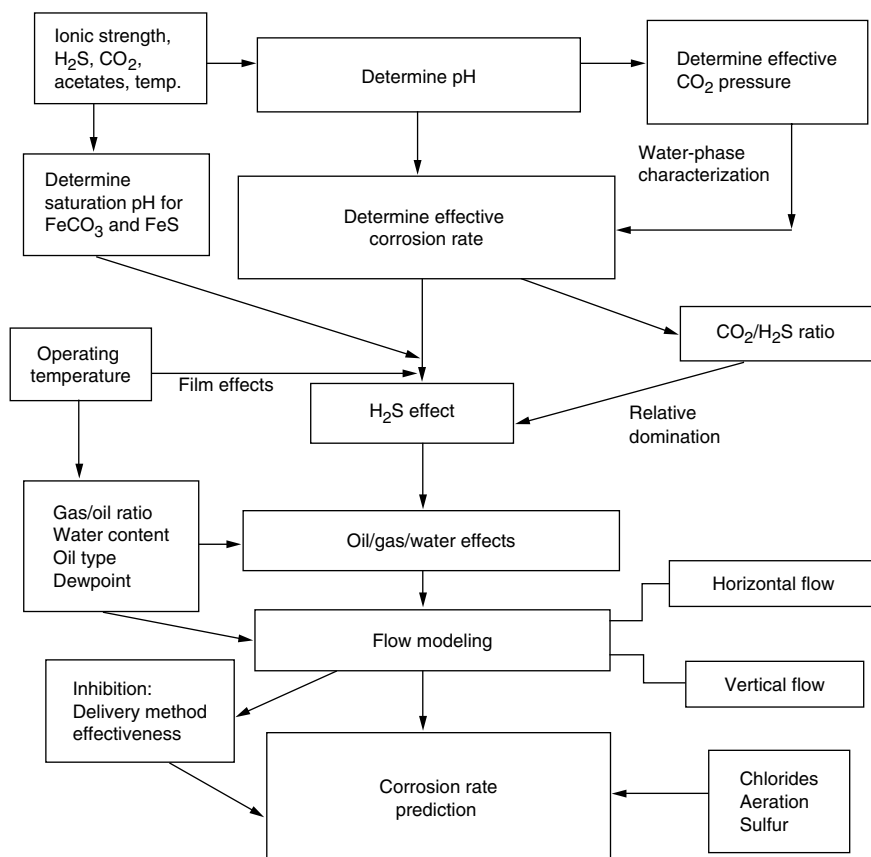

Fig. 2 Corrosion rate prediction flow chart. Source: Ref 9

Fig. 3 In situ pH determination for production environments. meq/L, milliequivalents per liter. Source: Ref 22

temperature (Ref 24). Consequently, pH determination can be represented as:

$$\text{pH}1 = \text{C}1 - \log(p_{\text{H}_2\text{S}} + p_{\text{CO}_2})$$

(Temperature = 20 °C, or 68 °F) (Eq 6)

If $\text{HCO}_3^- > 0$, then:

$$\text{pH}2 = \text{C}2 - \log(p_{\text{H}_2\text{S}} + p_{\text{CO}_2}) + \log(\text{HCO}_3^-)$$

(Temperature = 20 °C, or 68 °F) (Eq 7)

where C1 and C2 are constants, $p_{\text{H}_2\text{S}}$ and p_{CO_2} are partial pressures in bars, and HCO_3^- concentration is represented in milliequivalents per liter (meq/L) (61 mg/L).

The effective CO_2 partial pressure is used to determine an initial corrosion rate for CO_2 -based corrosion. The corrosion rate so obtained is modified to account for the formation of a FeCO_3 film (Fe_3O_4 at higher temperatures) whose stability varies as a function of the operating temperature. The scale correction factor shown in Fig. 1 is used to determine the initial corrosion rate from the nomogram in Fig. 1 (Ref 2). It is generally estimated that this corrosion rate presents a maximum corrosion rate, even though it has been reported that the rate computed by the nomogram is reached or exceeded in systems with high flow rates. It is important to recognize that this corrosion rate has to be modified to account for the effect of other critical variables in the system. Further, this rate does not indicate modality (general or localized) but rather represents the maximum rate of attack.

As indicated earlier, it is necessary to superposition effects of other critical system parameters on base corrosion rate. The flow chart in Fig. 2 provides the lists of sequential effects that are important from the standpoint of corrosivity determination. In addition to the system pH, these include:

- H_2S partial pressure
- Maximum operating temperature
- Dissolved chlorides
- Gas-to-oil ratio
- Water-to-gas ratio/water cut
- Oil type and its persistence
- Elemental sulfur/aeration
- Fluid velocity
- Type of flow

Fig. 4 Corrosion rate of steel as a function of pH and velocity. Source: Ref 13

The following sections discuss the effects of these parameters on corrosivity and provide information explaining why it is critical to examine the parameter interactions prior to capturing the synergistic effects of these parameters on corrosion.

Role of H_2S . In recent years, oilfield production environments have been characterized by the increasing presence of H_2S and related corrosion considerations. Even though H_2S is probably the most significant concern in current-day corrosion and cracking evaluation, the role of H_2S in corrosion in steels has received much less attention when compared to the widely studied CO_2 corrosion (Ref 25). However, H_2S -related corrosion and cracking has remained one of the biggest concerns for operators involved in production, because of the significance of H_2S -related damage (Ref 26).

For the model described herein, in addition to its contribution in pH reduction, H_2S has a threefold role:

- At very low levels of H_2S (<0.01 psia), CO_2 is the dominant corrosive species, and at temperatures above 60 °C (140 °F), corrosion and any passivity are a function of FeCO_3 formation-related phenomenon; the presence of H_2S has no realistic significance.
- In CO_2 -dominated systems (Ref 25, 27), the presence of even small amounts of H_2S (ratio of $p_{\text{CO}_2}/p_{\text{H}_2\text{S}} > 200$) can lead to the formation of an iron sulfide scale called mackinawite at temperatures below 120 °C (250 °F). However, this particular form of scaling, which is produced on the metal surface directly as a function of a reaction between Fe^{2+} and S^{2-} , is influenced by pH and temperature (Ref 26). This surface reaction can lead to the formation of a thin surface film that can mitigate corrosion. The authors are currently

Fig. 5 Effect of gas composition and temperature on corrosion rate of steel. Source: Ref 28

pursuing laboratory studies to characterize the stability and formation of mackinawite in sour systems.

- In H_2S -dominated systems (ratio of $p_{\text{CO}_2}/p_{\text{H}_2\text{S}} < 200$), there is a preferential formation of a metastable sulfide film in preference to the FeCO_3 scale; hence, there is protection available due to the presence of the sulfide film in the range of temperatures 60 to 240 °C (140 to 465 °F). Here, it is initially the mackinawite form of H_2S that is formed as a surface adsorption phenomenon. At higher concentrations and temperatures, mackinawite becomes the more stable pyrrhotite. However, at temperatures below 60 °C (140 °F) or above 240 °C (465 °F), the presence of H_2S exacerbates corrosion in steels, because the presence of H_2S prevents the formation of a stable FeCO_3 scale (Ref 7, 28). Further, it has been observed that the FeS film itself becomes unstable and porous and does not provide protection. Also, the scale factor applicable for CO_2 corrosion with no H_2S (shown in Fig. 1) becomes inapplicable. Even though there is agreement among different workers that there is a beneficial effect of adding small amounts of H_2S at approximately 60 °C (140 °F), divergent results at higher concentrations and higher temperatures have been presented (Ref 7, 10).

The effect of H_2S adopted in the predictive model reflects work from Ref 28 for CO_2 -dominated systems. Figure 5 (Ref 28) shows the combined effects of temperature and gas composition on the corrosion rate of carbon steels. Figure 6 (Ref 7) shows the effect of varying degrees of H_2S contamination on CO_2 corrosion. It is to be noted that the role of H_2S in CO_2 corrosion is a complex issue governed by film stability of FeS and FeCO_3 at varying temperatures and is an area of further active research by the authors. For additional information on CO_2 effect on carbon and chromium alloy steels, see Ref 29.

Temperature Effects. Temperature has a significant impact on corrosivity in $\text{CO}_2/\text{H}_2\text{S}$ systems. Corrosion rate as a function of different levels of CO_2 and temperature is given in Fig. 7 (Ref 2). It has to be noted that once the corrosion products are formed, there is a significant mitigation in corrosivity. It is also apparent that the

Fig. 6 Effect of H_2S and temperature on corrosion rate in pure iron. Source: Ref 7

carbonate film is more stable at higher temperatures and affords greater protection at higher temperatures. Figure 7 also shows that at temperatures beyond 120 °C (250 °F), the corrosion rate is almost independent of the CO₂ partial pressure of the system. The carbonate film may, however, be weakened by high chloride concentrations or can be broken by high velocity. In H₂S-dominated systems, because of the fact that no carbonate scale may be formed and that the FeS film becomes porous and unstable at temperatures beyond 120 °C (250 °F), significant localized corrosion may be observed.

Effect of Chlorides. Produced water from hydrocarbon formations typically contains varying amounts of chloride salts dissolved in solution. The chloride concentration in this water can vary considerably, from zero to a few parts per million (ppm) for condensed water, to saturation in formation waters having high total dissolved salts/solids. In naturally deaerated production environments, the corrosion rate increases with increasing chloride ion content over the range of 10,000 to 100,000 ppm (Ref 30). The magnitude of this effect increases with increasing temperature over ~60 °C (150 °F). This combined effect results from the fact that chloride ions in solution can be incorporated into and penetrate surface corrosion films, which can lead to destabilization of the corrosion film and

increased corrosion. This phenomenon of penetration of surface corrosion films increases in occurrence with increases in both chloride ion concentration and temperature.

Effect of Bicarbonates. Bicarbonates in the operating environment have a significant impact on corrosion rates. High levels of bicarbonates can provide higher pH numbers, leading to corrosion mitigation even when the partial pressures of CO₂ and H₂S are fairly high. There is a natural inhibitive effect from the presence of bicarbonates, which can be present in substantial quantities in formation waters (up to 20 meq/L) (Ref 30). Condensed water in production streams typically contains no bicarbonates.

Velocity Effects. Next to the corrosive species that instigate corrosion, velocity is probably the most significant parameter in determining corrosivity. Fluid-flow velocities affect both the composition and extent of corrosion product films. Typically, high velocities (>4 m/s, or 13 ft/s, for noninhibited systems) in the production stream lead to mechanical removal of corrosion films, and the ensuing exposure of the fresh metal surface to the corrosive medium leads to significantly higher corrosion rates. Corrosion rate as a function of flow velocity and temperature is shown in Fig. 8 (Ref 13).

In multiphase (i.e., gas, water, liquid hydrocarbon) production, the flow rate influences the corrosion rate of steel in two ways. First, it determines the flow behavior and flow regime. In general terms, this is manifested as static conditions (i.e., little or no flow) at low velocities, stratified flow at intermediate conditions, and turbulent flow at higher flow rates. One measure that can be used to define the flow conditions is the superficial gas velocity. In liquid (oil/water) systems, this is replaced with the liquid velocity.

Velocities less than 1 m/s (3.3 ft/s) are considered static. Under these conditions, corrosion rates can be higher than those observed under moderately flowing conditions. This occurs because under static conditions, there is no natural turbulence to assist the mixing and dispersion of protective liquid hydrocarbons or

inhibitor species in the aqueous phase. Additionally, corrosion products and other deposits can settle out of the liquid phase to promote crevice attack and underdeposit corrosion.

Between 1 and 3 m/s (3.3 and 9.8 ft/s), stratified conditions generally still exist. However, the increased flow promotes a sweeping away of some deposits and increasing agitation and mixing. At 5 m/s (16.4 ft/s), corrosion rates in noninhibited applications start to increase rapidly with increasing velocity. Data shown in Fig. 9 demonstrate the effects of velocity on corrosion rate for both inhibited and non-inhibited systems. For inhibited applications, corrosion rates of steel increase only slightly between 3 to 10 m/s (9.8 to 33 ft/s), resulting from mixing of the hydrocarbon and aqueous phases. Above approximately 10 m/s (33 ft/s), corrosion rates in inhibited systems start to increase due to the removal of protective surface films by the high-velocity flow.

Flow-related effects on corrosivity have been linked to the developed wall shear stress and have been an area of intense research (Ref 31). Flow-induced corrosion is a direct consequence of mass and momentum transfer in a dynamic flow system, where the interplay of inertial and viscous forces is responsible for accelerating or decelerating metal loss at the fluid/metal interface. Another relevant aspect of flow- or velocity-induced corrosion is erosion-corrosion (Ref 32), which refers to the mechanical removal of corrosion-product films through momentum effects or through impingement and abrasion. Guidelines for velocity limits with respect to erosional considerations are given in API 14E in terms of the density of the fluid medium (Ref 33).

Importance of Water/Gas/Oil Ratios. It is important to account for the beneficial effects of hydrocarbons in a flowing system. Systems are characterized as oil dominated or gas dominated

Fig. 7 Corrosion rate as a function of temperature and CO₂ pressure. Source: Ref 2

Fig. 8 Corrosion rate as a function of velocity and temperature. Source: Ref 13

Fig. 9 Effect of gas velocity on corrosion rate

on the basis of the gas/oil ratio (GOR) of the production environment. If the environment has a $GOR < 890 \text{ m}^3/\text{m}^3$ (5000 scf/bbl in English units) (Ref 34), the tendency for corrosion and environmental cracking is often substantially reduced. This is caused by the possible inhibiting effect of the oil film on the metal surface, which effectively reduces the corrosivity of the environment. However, the inhibiting effect is dependent on the oil phase being persistent and acting as a barrier between the metal and the corrosive environment. The persistence of the oil phase is a strong factor in providing protection, even in systems with high water cuts. In oil systems with a persistent oil phase and up to 45% water cut, corrosion is fully suppressed, regardless of the type of hydrocarbon (Ref 10). Relative wettability of the oil phase versus the water phase has a significant effect on corrosion (Ref 35). Metal surfaces that are oil-wet show significantly lower corrosion rates (Ref 36).

The degree of protection provided by oil films can be quantified only as a function of water cut and velocity. Figure 10 shows data that relate the acid number of the crude to oil wettability, and Fig. 11 shows corrosion rate as a function of produced water content for different crude oil/produced water mixtures. In oil systems, the water cut acts in synergy with the oil phase to determine the level of protection from the hydrocarbon phase. However, at very low water cuts (less than 5%), corrosive severity of the environment is lessened due to the absence of an adequate aqueous medium required to promote the corrosion reaction.

Aeration/Sulfur Effects. The presence of oxygen significantly alters the corrosivity of the environment in production systems. How the presence of oxygen can significantly increase corrosion rates due to acceleration of anodic oxidation is discussed in Ref 37. While corrosion rate increases with oxygen, rate of oxygen reduction as a cathodic reaction is further exacerbated by:

- Increase in operating temperature
- Increased fluid flow, leading to increased mass flow of oxygen to the metal surface
- Increasing oxygen concentration

Data showing increases in corrosion rate as a function of oxygen concentration for differing temperatures are shown in Fig. 12 (Ref 37).

In systems containing high levels of H_2S , elemental sulfur is often found to be present. Its presence can significantly increase the corro-

sivity of the production environment with respect to weight-loss corrosion and localized corrosion. Presence of sulfur is similar to that of having oxygen in production systems, in that it can be a strong oxidizing agent and can lead to significantly increased local attack. Sulfur can directly combine with iron to form FeS and can lead to significant metal loss in a localized mode.

Effect of Multiphase Flow on Corrosion. Corrosion in multiphase systems stems not only from electrochemical interaction of the corrosive species (CO_2 , H_2S , etc. dissolved in an aqueous medium) with steel, leading to metallic oxidation and subsequent metal loss, but also from the adverse impact of the flowing medium on the corroding surface and environment. This situation is significantly exacerbated through flow-related effects where high wall shear stresses, developed as a consequence of different flow regimes, can lead to accelerated corrosion. Significant research has been conducted to understand the role of various hydrodynamic parameters, primarily the wall shear stress, on corrosion.

Some research has focused on systems in slug flow and correlated corrosion rate as a function of wall shear stress (Ref 38). This work focused mainly on sweet water corrosion, and the data provided empirical relationships for multiphase systems. One such equation for corrosion rate prediction in horizontal multiphase slug flow is:

$$CR = 31.15 \text{ } Cr_{\text{freq}} \text{ } Cr_{\text{crude}} \times \left[\frac{\Delta P}{L} \right]^{0.3} v^{0.6} p_{\text{CO}_2}^{0.8} T e^{\left(-\frac{2671}{T} \right)} \quad (\text{Eq 8})$$

where, CR is the corrosion rate in mm/yr, $\Delta P/L$ is the pressure drop gradient per unit length, v is the viscosity in centipoise, p_{CO_2} is the partial pressure of CO_2 in bar, T is the temperature of the system in $^\circ\text{C}$, and Cr_{freq} is the normalized factor to account for slug frequency, defined as:

$$Cr_{\text{freq}} = 0.023 F + 0.214 \quad (\text{Eq 9})$$

where F is the slug frequency.

Equation 10 provides a definition for corrosion rate from the crude, Cr_{crude} (in mm/yr), in terms of total acid number of the crude (acid number is a number on an interval scale used to characterize various acids in the crude, such as

naphthenic acid). Please see the cited reference for further information:

$$Cr_{\text{crude}} = \frac{10^{(\log(\text{Acid number} \cdot \% \text{ nitrogen}) + 0.38)}}{24,000} \quad (\text{Eq 10})$$

Researchers (Ref 31) performed experiments with three different systems, including a horizontal pipe flow system, a jet impingement setup, and a rotating cylinder electrode apparatus. They were able to establish a correlation between corrosion rate and wall shear stress as:

$$R_{\text{COR}} = a \tau_w^b \quad (\text{Eq 11})$$

where R_{COR} is the corrosion rate in mm/yr, τ_w is the wall shear stress in N/m^2 , and a and b are constants.

A related research effort in this area (Ref 39) derived a correlation from a database of 2500 points with various steels between corrosion rate, CR_T , and wall shear stress, S :

$$CR_T = K_T \cdot f_{\text{CO}_2}^{0.6} \cdot f(S) \quad (\text{Eq 12})$$

$$f(S) = \left[\frac{S}{19} \right]^{0.15 + 0.03 \log(f_{\text{CO}_2})} \quad (\text{Eq 13})$$

where CR_T is the corrosion rate in mm/yr as a function of CO_2 fugacity and shear stress at a given temperature, f_{CO_2} is fugacity of CO_2 in bar, S is shear stress in Pa, and K_T is a constant.

Efforts to characterize corrosion in flowing systems require modeling thermodynamics, phase behavior, mass transfer, and momentum-transfer effects. Mass transfer in a system relates to the movement of corrosive species between the pipe wall and the bulk flowing medium. The wall shear stress can be used as the primary hydrodynamic parameter representing momentum-transfer effects as a consequence of the inertial and frictional forces applied by a turbulent flowing medium on the pipe material surface (Ref 40). Because mass-transfer and momentum-transfer effects are interdependent, a change in wall shear stress will affect mass transfer and also impact flow regimes and corrosion rates.

Flow Modeling of Multiphase Systems. As indicated in the previous section, multiphase flow systems present a tremendous challenge from the standpoint of corrosion evaluation and prediction because of the need to determine the role of important environmental, flow, and metallurgical variables and underlying mechanisms of corrosion. Modeling of multiphase flowing systems is a powerful tool for understanding internal corrosion in pipelines, because it facilitates assessment of liquid holdup, determination of wall shear stresses, prediction of flow patterns, accurate calculation of pressure drops in piping, computation of the critical angle for liquid accumulation in a pipeline, and the prediction of phase behavior of water for both horizontal and inclined flow over moderately hilly terrains. Although a detailed review of flow modeling is beyond the scope of this article, a number of papers on this subject have been published, and these should be referred to for additional information (Ref 1–5, 41–52).

Transmission Pipeline Scenario. For natural gas transmission pipelines, the highest number of incidents causing significant downtime or loss of life in 2003 were caused by internal corrosion. As reported in the data accumulated by the United States Office of Pipeline Safety and reproduced in Table 1, internal corrosion was reported as the reason for a loss in excess of \$3.7 million in 2002 and amounted to more than 17% of damages due to all causes.

Internal corrosion in dry gas pipelines normally occurs when upstream gas processing/dehydrating units deliver gas that does not meet quality specifications with regards to the water content of the gas or dewpoint. It is under these circumstances that liquid water accumulates at

certain sections in a piping segment and, in some cases, has been known to cause corrosion-driven pipeline failure.

Internal corrosion in pipelines is difficult to locate and measure due to a number of factors. Most internal corrosion-detection measures require access to the internals of a pipe for in-line inspection as well as visualization tools such as in-line pigs; however, a substantial portion of the pipeline does not allow in-line inspection, mostly due to physical and mechanical constraints. Other inspection techniques, such as ultrasonic technology and radiography, are implemented to measure wall thickness and estimate metal loss from the outside of a pipe, but excavation, cleaning, and other physical constraints allow for only a small area to be inspected at a time.

The ICDA approach to evaluate the likelihood of water accumulation and internal corrosion, and to identify critical zones, can enhance the actual measurement techniques and ensure safe operation of natural gas pipelines. A detailed analysis of critical locations where water would most likely accumulate provides information about relevant parts, from the perspective of a potential for corrosion damage of the piping system (Ref 53, 54).

A two-tiered procedure for the ICDA approach has been outlined in Ref 55. The first step deals with identifying zones with inclination greater than the critical angle, and selecting the first such segment from the downstream end of the pipeline (most downstream). Performing a detailed examination of this segment for corrosion forms the second step. If, on inspection, no corrosion is found, it is concluded that corrosion further downstream of that segment is unlikely (because they all are noncritical, and the segment

identified as critical has no corrosion). Performing inspection on other susceptible segments, upstream of the initial location, will provide integrity information for the pipe between these two points. Progressing upstream, identifying susceptible segments and inspecting these segments, the entire pipeline is assessed for internal corrosion (Ref 40, 56).

If the locations identified as most susceptible to internal corrosion are determined by examination to be free from damage, the integrity of a significant part of the pipeline system is assured. If such locations are found to be experiencing corrosion, a potential integrity problem is identified, and remedial action may be prescribed.

Real-Time Corrosion Measurement and Monitoring

One of the problems associated with corrosion control is that corrosion is commonly dealt with in a historical sense, after the damage has occurred and with no opportunity to prevent future reoccurrence. In this light, corrosion measurements are usually relegated into reactive, maintenance functions. Off-line monitoring data can be viewed neither real-time nor alongside the process conditions that often initiate high-level corrosion activity. Recent innovations in monitoring technology enable the corrosion engineer to interact directly with the new on-line, real-time world of process control/optimization and asset management, leading the way to change for those that embrace, use, and promote these new technologies.

Developments in corrosion-monitoring technologies have increased the accuracy of data, promoting its relevance and value to the ultimate goal of increasing productivity by reducing corrosion damage, failures, and unplanned outages, thus decreasing downtime and increasing run time. Improved enterprise communications have also provided on-line connectivity for corrosion engineers, bringing them in closer contact with the frontline people that control processes and manage these facilities. Under this new paradigm, corrosion becomes another real-time process variable. The corrosion measurement device becomes the “tachometer” for the facility, showing in real-time when processes go awry and prompting remedial action before substantial damage occurs.

Off-Line Methods

Corrosion measurement methods in use today (2006) include simple, off-line techniques such as weight-loss coupon analysis. However, this provides only a retrospective status check rather than a means of active real-time process control. Off-line measurement methods also include such general corrosion measurement techniques as electrical resistance (ER) and linear polarization resistance (LPR) methods described in ASTM G 96 (Ref 57). These systems are able to operate in

Table 1 Summary (year 2002) of the causes of damage to transmission pipelines

Cause	No. of incidents	% of total incidents	Property damages, U.S. dollars	% of total damages	Fatalities	Injuries

stand-alone mode, providing spot corrosion data via battery-powered, field-mounted instruments, often with logging capability.

The flexibility of installing off-line systems in remote locations is somewhat offset by the fact that data are available only periodically, and there is an overhead in personnel time to manually download and process the data. Furthermore, such systems are often limited by shrinking allocations for corrosion control in tightening maintenance budgets. Once gathered, postprocessing of the corrosion data is often performed in computerized spreadsheet format. In most of these cases, the data are viewed after the corrosion has occurred and do not easily take into account process variables (e.g., temperature, pressure, flow rate, chemical feed rate, etc.). It is the corrosion engineer's burden to find and access this information, manually integrate it with the historical corrosion data, and present the findings in an after-the-fact report with recommendations.

On-Line Corrosion Measurement

In some cases, off-line LPR or ER measurements can be taken on-line. By this, it is usually meant that the corrosion measurement signal, rather than going to a local data-logging device, is channeled (often by hardwire) back to a safe area and then through the company network. Normally, this is performed with corrosion data from multiple points going back to a stand-alone computer (a dedicated corrosion server or simply a corrosion engineer's workstation). There can be substantial infrastructure costs associated with establishing this separate data channel that are beyond the capabilities of most corrosion-control budgets. For example, in some cases, the cost of hardwiring LPR or ER units in a plant environment can exceed the actual cost of the corrosion devices by up to a factor of 10. This is far from an optimal situation for acceptance of on-line corrosion-monitoring technology.

Even with on-line systems, the data are still commonly viewed or analyzed after-the-fact, which does not automatically include the ability to correlate the corrosion rate to specific process events, unless this is done manually by the corrosion engineer. Then, the corrosion engineer has to provide the process engineer or manager the "bad news" after a point where corrective action can be easily implemented.

New Technology for Real-Time On-Line Monitoring

Modern field corrosion monitoring now includes a broad range of techniques used to evaluate the degradation of metallic materials. These techniques can be divided into two distinct groups: namely, those providing indications of the cumulative damage sustained (retrospective) and those providing indications of the prevailing corrosion rate (usually on-line and continuous). These techniques are applicable

with virtually all metallic materials and are commonly grouped as:

- **Cumulative-loss techniques:** weight-loss coupon, electrical resistance, ultrasonic thickness measurement, and other non-destructive examination methods (e.g., radiography). The cumulative-loss techniques will show signs of change only when sufficient corrosion has been sustained to cause a change in the bulk material properties. As such, most are used off-line and do not provide real-time data, requiring measurement cycles of days to weeks.
- **Corrosion rate techniques:** linear polarization resistance, harmonic distortion analysis (HDA), and electrochemical noise (EN). The corrosion rate techniques have a much higher resolution and short response time and have been developed to provide a fast assessment of the electrochemical rate processes taking place at the metal/environment interface. Measurements using these techniques take only a few minutes.

Experience with the most commonly used on-line techniques, such as LPR and ER, indicates that they are particularly good for detecting trends in uniform corrosion rates. In this capacity, they are looked upon as qualitative indicators of general corrosivity. That is to say that if the reading is going up, things are getting worse, and if the value is going down, things are getting better. Furthermore, these techniques are not sensitive to, nor can they differentiate between, both localized and uniform corrosion.

Advances in automated, multitechnique systems have made it possible to incorporate multiple measurements into a single instrument, thereby increasing accuracy to the point of being able to make quantitative measurements (e.g., LPR corrosion rate with B -value correction from HDA) and being able to differentiate the modality (pitting versus uniform corrosion) of the corrosion process (e.g., use of EN). Furthermore, this can be done on a time scale of minutes, which is consistent with modern process-control approaches. This latter point is extremely important, because it now is possible to provide quantitative corrosion rate and modality measurements and deliver them via the same (and existing) communications protocols (4 to 20 mA, RS-485, RS-232, and HART) that are already in place and used to acquire process variables through supervisory control and data acquisition or distributed control systems.

The importance of the aforementioned advances is that the corrosion engineer can now be "plugged into" the same on-line, real-time channel that is used for process control and optimization and facilities asset management. Corrosion data are automatically commingled and displayed with process data. The corrosion engineer is no longer relegated to a stand-alone function. He/she can see the same real-time process data that the process engineer sees, and the process engineer has access to the on-line corrosion rate that the corrosion engineer

sees, enabling use of these data together as key performance indicators. Both engineering functions can now work together in a new way. The process engineer uses the corrosion signal as another variable that needs to be optimized (e.g., minimize asset damage, increase production while controlling damage to acceptable levels, extend allowable run time, and manage process to minimize inspection requirements).

Implementation of On-Line, Real-Time Corrosion Rate Systems

The use of corrosion rate techniques such as LPR offers sensitivity and high-resolution assessment of the corrosion current that is a direct consequence of the instantaneous corrosion process. Its value is directly related to the rate of the metal loss. The electrochemical monitoring methods have been developed specifically to estimate the corrosion current. The relationship between the polarization resistance measurement and the corrosion current is given by the Stern-Geary relationship:

$$i_{\text{corr}} = B/R_p \quad (\text{Eq 14})$$

where R_p is the polarization resistance, B is the Stern-Geary factor, and i_{corr} is the corrosion current density.

One limitation with commonly used LPR technology is that this technique cannot directly measure the proportionality factor (B value), which has led to its qualitative use in many cases. Most field corrosion instruments use a factory-set defaulted B value of 25 to 30 mV. However, recent studies have shown that the actual value for this proportionality factor can vary from less than 3 to over 100 mV, depending on the nature of the system, the reactive species (which can change from time to time), and even from system to system (Table 2) (Ref 58).

Incorporation of additional newer electrochemical techniques, such as HDA, into a field device provides capture of a more complete frequency response to provide values for the corrosion current, the characteristic anodic and cathodic Tafel coefficients, and hence an actual value for the Stern-Geary factor. The incorporation of the real-time B value with the corrosion current thus provides a more accurate corrosion rate measurement. More detailed information on the role of Tafel and B value in corrosion processes can be found in the article "Corrosion in Petroleum Production Operations" in this Volume.

Assessment of Localized (Pitting) Corrosion

Additional techniques can also be included, such as EN, to further augment and complete an automated corrosion measurement cycle. The EN method is used proactively to identify periods when the corrosion processes become unstable (usually associated with localized corrosion phenomena—pitting, crevice

corrosion, and stress-corrosion cracking) and thus recognizes when the probability of localized corrosion is high. When corrosion changes from uniform to pitting, the characteristics of the current and potential fluctuations change dramatically over orders of magnitude. When normalized to the average corrosion current over the period, these noise signals can be analyzed and displayed real-time in much the same way that they can describe noise in any electrical system, which is the basis of a pitting factor value. From a facilities corrosion-control perspective, this is important, because the technique provides an early warning of incipient localized corrosion events so that action can be taken at the process control level before substantial pitting damage occurs.

Discussion of Case Studies in Modern Multitechnique Electrochemical Corrosion Monitoring

Case Study No. 1: Measurement of Corrosion in Multiphase Pipeline Environments (Ref 59). The use of on-line, real-time multi-technique monitoring methods has been able to

provide quantitative corrosion rate trends and indications of modality in systems containing oil and water in combination with corrosive gases. As shown in Fig. 13, the combination of LPR, HDA, and EN provides a more complete representation of the corrosion taking place in both the liquid and vapor phases in a dehydrated gas pipeline environment containing condensing water and glycol, methane, and carbon dioxide. When compared to corresponding coupon data taken on the same exposure interval, it can be seen that the uniform corrosion rates are approximately a factor of 10 higher in the liquid phase than in the vapor. The rates obtained by monitoring were very similar to those independently determined by mass-loss measurements on the coupons. Furthermore, and perhaps more importantly, the mode of corrosion in the condensing vapor phase was found to be pitting corrosion. The use of EN data taken during the automated measurement cycle showed high values of pitting factor throughout the exposure period. Such data provide a basis for remedial actions before substantial damage has occurred.

Case Study No. 2: Use of Field System for Determining Inhibitor Dosage Requirements (Ref 60). In most cases, inhibitor dosages are

determined through laboratory studies and then migrated to the field through a relatively slow iterative process. A gas pipeline system with very high H_2S concentration and severe corrosion was monitored on a real-time basis to quickly assess corrosivity and establish an optimal inhibitor dosage. At the startup of operations, very high dosages were used. Figure 14 shows the differences in corrosion rate without and with B -value adjustment (from HDA data). The B value for this sour gas system was determined to be approximately 120 mV, approximately four times the default value in most field instruments. Therefore, the actual corrosion rate was four times the value originally believed, based on simple LPR measurements. A real-time pipeline inhibitor dosage study was conducted in terms of percent inhibitor efficiency while switching the inhibitor injection off and then monitoring corrosion at various inhibitor dosages attained by varying the injection rate. As a result of this effort, the pipeline operator was able to reduce the dosage substantially, with an associated cost saving of approximately 60%.

Case Study No. 3: Microbiological/Corrosion in a Water-Handling System (Ref 61). Figure 15 shows a combination plot of corrosion rate (corrected for a B value of only 8 mV versus the standard 25 to 30 mV), pitting factor, and sulfate-reducing bacteria (SRB) growth versus time for a period of approximately 1 week in a simulated oilfield water injection system. The graph shows the variations in corrosivity that occur as a result of production of H_2S from SRB activity, short-term operational conditions (periodic system aeration), formation of biofilms with increasing SRB counts, and the long-term effects on pitting tendencies as observed by pitting factor readings. First of all, the measured B values were very low as a result

Table 2 Role of Tafel and B value in corrosion processes

Anodic Tafel (β_a), mV	Cathodic Tafel (β_c), mV	B value, mV	Physical mechanisms	Practical examples
60	60	1–13	Both processes activation controlled	Deaerated environments or those with depolarizing species (e.g., sulfides)
60	∞	18–30	Anodic process activation controlled; cathodic process diffusion controlled	Aerated environments (e.g., fresh water, seawater, or brine)
120	∞	50–80	Anodic process activation controlled; cathodic process diffusion controlled (anodic slope different)	Mixed multiphase (oil/water) conditions; inhibitor or organic films on metal surface
∞	∞	>100	Severe anodic and cathodic diffusion limiting	Condensing vapor environments, thin liquid films on corroding surface

Fig. 14 Corrosion rate during inhibitor injection on/off cycle in a sour gas pipeline. Note: Measured corrosion rate with default B value and measured B value from harmonic distortion analysis. Source: Ref 60

Fig. 15 On-line, real-time correlation between corrosion rate (left scale), pitting tendencies (right scale), and sulfate-reducing bacteria (SRB) growth (dotted curve). Note: Annotations for short-term process information for H_2S concentration and imposed aeration. Source: Ref 61

of the presence of biologically produced H_2S in the system and sulfide films on the steel surfaces. The low B -value readings demonstrate the inaccuracy at a factor of 3 of noncorrected LPR corrosion rates. Secondly, corrosion and pitting factor varied considerably with operating conditions, with periodic increases in localized corrosion during each aeration cycle. Over the longer term, the system developed a considerable tendency for localized corrosion (high pitting factor) near the end of the monitoring period that matched the rise in sessile SRB count on the metal surface. This is likely the result of formation of a biofilm and the local variations in corrosion tendencies on filmed and nonfilmed areas. Additional measurements of resistance were also made that indicated the buildup of FeS surface films during the exposure period. None of these

measurements would have been possible without the automated, multitechnique monitoring capabilities.

Summary

Internal corrosion in natural gas pipelines is a complex phenomenon requiring thermodynamic, electrochemical, and fluid dynamic analyses and characterizations. Corrosion prediction and ICDA models have been described and represent effective methodologies to develop a program to prevent pipeline corrosion failures. The ICDA method is applicable to gas transmission pipelines that may potentially suffer from episodic upsets of wet gas or liquid water carryover. Locations along a dry gas

pipeline that are identified as most likely to accumulate water are examined in detail, and if these locations have not corroded, it would be reasonable to infer that other locations, less likely to accumulate the water electrolyte, may be considered free of corrosion.

On-line, real-time corrosion monitoring may be performed using a combination of electrochemical techniques that provide complementary information on both general and localized corrosion in a broad range of pipeline and process environments. Based on the data and information arising from numerous studies, the following conclusions, specifically related to petroleum production and transmission pipeline environments, may be drawn:

- Real-time corrosion measurement of both general and pitting tendencies has provided valuable insights into the corrosion behavior of steel and other metallic materials in low water cut, dehydrated, multiphase, and vapor-phase environments.
- The ability to measure the B value (Stern-Geary factor) on-line and in real-time has dramatically improved the accuracy of corrosion rate measurement, thus assisting appropriate and cost-efficient use of chemical treatments.
- Corrosion rates in multiphase (oil/brine/gas) environments have been found to exhibit widely varying corrosion rates between 0.001 to over 2.5 mm/yr (0.04 to over 100 mils/yr), depending on the conditions imposed (e.g., flow, chemical composition).
- In liquid-phase environments, the highest corrosion rates have been associated with agitation that produced severe liquid-phase turbulence. In most cases, corrosion in the liquid phase is uniform in nature and shows low pitting factor values.
- In heavy oil/brine/ CO_2 environments, high pitting factor values and visual signs of localized corrosion have been observed in the liquid phase, possibly arising due to partial coverage of the heavy oil on the metal surface.

- Vapor-phase environments typically exhibit a general corrosion rate 1 to 2 orders of magnitude lower than that found in liquid-phase environments. However, higher corrosion rates can result from agitation or turbulent flow, which likely provides increased water availability in the vapor phase.

In summary, it is evident that corrosion behavior in pipeline environments has a number of influencing factors that can vary with time and so cause a dynamically changing corrosion condition. Inspections and off-line measurements do not afford the operator the opportunity to correlate corrosion excursions with operating and process parameters, making corrosion control a difficult proposition. This illustrates the importance of implementing an appropriate and correspondingly dynamic means of corrosion appraisal to help manage chemical and other corrosion-prevention treatments and to maximize the availability of the pipeline infrastructure.

Inspection, Data Collection, and Management

Sam McFarland, Lloyd's Register

HUGE AMOUNTS OF TIME AND MONEY ARE INVESTED in designing, constructing, commissioning, and operating major petroleum and petrochemical installations. To safeguard this investment and to ensure adequate prevention of adverse effects on health, safety, and the environment, and to meet legal requirements, plant owners/operators deploy other resources to monitor and maintain their plants in a safe and efficient condition. Inspection is one of the key resources used and, if properly planned and deployed, can be a very effective means of ensuring that the plant is kept in a safe condition, thereby avoiding accidents or unexpected plant incidents.

Historically, requirements for inspection evolved over the years in a generally unstructured way, prompted by requirements from design codes and from periodic legislation raised by various industry and governmental bodies, often in response to major plant incidents. A set of inspection requirements at the time of construction and commissioning was generally required by the design codes with some guidance on periodic inspection once in service. These inspection requirements became more formalized as knowledge of likely deterioration mechanisms improved and as plant failures became better understood. This led to the setting of standard periods of inspection for a range of plant equipment, largely triggered by instances of boiler and steam system failures.

By the 1980s, instances of catastrophic plant failure were much reduced due to better materials, tighter control of design, improved fabrication quality assurance, appropriate maintenance, valid inspections, better plant process control, and so forth. This improved track record and the continued drive for improved profitability turned the focus away from set periods of inspection (prescriptive regime) to the setting of inspection periods that reflected the true condition and nature of the equipment and its specific service conditions (risk-based regime). Allied to this, developments in equipment, methods, and procedures for noninvasive inspection made it possible (and attractive in some cases) to carry out meaningful inspections while the plant was still

running using advanced nondestructive examination (NDE) techniques.

Inspection can generate large quantities of data in terms of visual inspection reports, NDE reports, photographs, radiographs, measurements, and live monitoring data. To turn inspection data into meaningful knowledge regarding fitness for service requires further data in terms of design, operation, construction, process, chemistry, maintenance records, and so forth. The requirements for handling such quantities of data in a form that is readily accessible, easily used, secure, and reliable has developed into a specialist subject of its own with proprietary systems and in-house developments available across various industries.

It is not possible in this article to cover all aspects of inspection and all items to which inspection is applied. This article concentrates almost exclusively on inspection related to pressure vessels and pipework, but many of the issues regarding inspection planning and particular techniques are also relevant to inspection of structures and other components. Excluded from consideration are related topics such as corrosion-monitoring devices, pressure testing, vibration monitoring, and pipeline pigging.

Inspection

Following a discussion of the general aspects associated with inspection, this section addresses:

- Inspection policy
- Inspection planning and procedures
- Inspection strategy
- Inspection methodology
- General preparation for inspection
- Invasive vs. noninvasive inspection
- Internal visual inspection
- Noninvasive inspection
- Inspection execution
- Risk-based inspection
- Inspection techniques (It should be noted that this topic is also discussed in the Appendix to this article, which reviews in greater detail the

commonly used inspection techniques in the petroleum and petrochemical industries.)

- Competence assurance of inspection personnel
- Inspection coverage
- Inspection periodicity
- Inspection anomaly criteria
- Assessment of fitness for purpose
- Reporting requirements

A subsequent major section in this article—"Data Collection and Management"—addresses data acquisition, reporting and trending, and review and audit.

General Aspects of Inspection

Inspection is carried out at different stages in a product's life cycle for a variety of reasons:

- At manufacture to check compliance of individual components with design and specification documents and standards
- At fabrication to check compliance of assemblies of components and general quality
- At commissioning to ensure that items have been installed in accordance with the specification
- In service to ensure that the component is performing as expected and is not suffering any undue deterioration
- When out of service to gain a detailed knowledge of the component's condition on which to base decisions concerning continued service

The reason for the inspection also partly dictates the method employed. At fabrication, full access is normally available and there are few restrictions on the types of inspection that can be carried out. In service on operating plant, there are restrictions for safety reasons, space constraints, and availability of support services so the range of available techniques is reduced. For example, x-ray radiography is commonly carried out at the fabrication stage but is generally not a realistic inspection method in service, where gamma radiography is generally employed due

to its portability and independence from an external power source.

If inspection requirements are considered early in the design stage, much can be done to aid future inspection efforts. Codes and standards generally call for access to be provided to allow for the component to be inspected periodically during service life, but this generally amounts to little more than the provision of access manways or inspection hatches. Greater consideration of inspection requirements at the design stage could result in measures to aid future inspectability of the component. This is particularly relevant to the ongoing development of non-invasive inspection techniques.

It may not be necessary to inspect every item. For example, items in low-pressure non-hazardous service may be operated with only a regular maintenance regime or on the basis of planned replacement after a set period in service. However, more significant plant items need to be subject to a scheduled inspection program to ensure their continued integrity and fitness for future service. To this end, it is important that a review is carried out on all plant items to assess those that pose the greatest risk. This process of risk assessment will identify the hazards associated with each item, the likelihood of failure, and the related mitigation measures required to manage the risk. This will also identify any low-risk items that can be safely excluded from the inspection program. Such items should be periodically reevaluated in case a future change in service condition or operation may make it necessary to add them to the inspection program.

The risk-assessment process will yield a list of plant items ranked in order of risk. This will provide a focus as to where the major inspection effort needs to be targeted. Once the hazard has been identified, it is important that an appropriate inspection technique is assigned for the detection, sizing, and monitoring of the anticipated deterioration mechanisms that could lead to this hazard condition. It is not possible to select a single inspection technique that will be suitable for all potential deterioration mechanisms. It is therefore important that the engineer specifying inspection requirements has full information regarding materials, process conditions, environment, and so forth to allow potential deterioration mechanisms to be determined and for appropriate inspections to be scheduled.

Inspection Policy

A clearly stated policy on the aims and objectives for inspection is a primary requirement. The policy, as a company document, forms the basis for subsequent reviews and audits of the inspection system, from initial planning and the inspection process itself to reporting and assessing results of inspection. Without a policy, it would be difficult to formulate a strategy or carry out a worthwhile audit.

Inspection Planning and Procedures

Standard specifications and methods of working have been established within industry to provide a structured approach for conducting and recording inspections (see, for example, Ref 1–9). These are very useful but cannot be relied on in themselves without the competence of engineers and inspectors to select appropriate inspection methods and for competent and experienced inspectors to be used to carry out the inspection.

The key factors in planning and carrying out an effective inspection are:

- All inspections should be properly planned by a qualified, competent person who can identify the likely deterioration mechanisms and the capabilities and limitations of appropriate inspection methods and procedures.
- The inspection should be included within the plant's overall operations and maintenance planning. This will ensure that sufficient time and resources are allocated for the inspection and that it is not seen as an add-on activity to be fitted in when possible.
- All relevant information should be made available to the inspector to enable the most appropriate inspection methods to be applied.
- The inspection should be targeted at detecting and sizing the types of defects that are expected in the component to be inspected, as far as can be ascertained by review of the available records.
- The inspection should be carried out in accordance with a clear written procedure or instruction that identifies the capabilities and limitations of the inspection technique in terms of detection and sizing of defects, the minimum training and qualification requirements for the person performing the inspection, the methods of reporting, and the responsibilities of each party in the inspection process.
- Any defects identified during the inspection should be recorded. The inspection procedure should include guidance on acceptability and reporting levels for types of defects. Any defects above the agreed threshold should be assessed for acceptability by a competent person. Allowance should be made for inaccuracies in the sizing of defects when carrying out an evaluation of the fitness for purpose of any chosen technique.
- The inspection personnel need to have the appropriate qualifications and training to ensure the competence and reliability of the inspection carried out (see the discussion "Competence Assurance of Inspection Personnel" later in this section).
- Where possible, the inspection personnel should have been tested and qualified on a test piece that realistically models the items to be inspected in service, with regard to access, orientation, and type of defect.
- The inspection function should be independent of normal maintenance functions to ensure that the inspector reports objectively.
- The choice of inspection technique must have a high probability of detection for the type and size of the defect expected and be suitable for the material and geometry of the component under test.
- The coverage of the inspection (for example, the amount of a weld or vessel shell to be inspected) should be chosen to give the required confidence in the integrity of the component for the required service life until the next scheduled inspection.
- The period between planned inspections should be justified and should take account of previous inspection findings as well as the risk profile for the equipment to be inspected.
- Adequate reporting and recording systems should be developed and maintained. Records should be available for the equipment throughout the life cycle of the plant, from fabrication through inspection, maintenance and monitoring carried out periodically during operation.
- The inspection program should be periodically reviewed to ensure its continued suitability as the plant ages, process conditions change, and systems deteriorate.

It is good practice (and in some regimes, compulsory) to develop a written scheme of inspection for each pressure system. Such a scheme should contain the following information:

- Those parts of the system that are to be examined
- Identification of the item of plant or equipment
- The nature of the inspection required (this may vary from out-of-service examination with the system stripped down, to in-service examination with the system running under normal operating conditions, depending on the applicable standards and legislative regime), including the inspection and testing to be carried out on any protective devices
- The preparatory work necessary to enable the item to be examined safely
- Specification of what inspection is necessary before the system is first used, where appropriate
- The maximum interval between inspections
- The critical parts of the system that, if modified or repaired, should be inspected by a competent person before it is used again
- The name of the competent person certifying the written scheme
- The date of the certification of the written scheme

Inspection Strategy

As mentioned previously, it is important that inspection activities are planned as far as

possible. Additionally, they should ideally be linked with associated maintenance and support functions within an integrated plan for the assurance of overall plant integrity. In this way, inspection will be treated as a key element of plant operation, not as a necessary evil or as an unplanned addition.

To this end, it is important that an inspection strategy is established that sets a methodical basis for setting of inspection requirements. An effective inspection strategy should address:

- Inspection methodology
- Inspection techniques
- Competence assurance of inspection personnel
- Inspection coverage
- Periodicity
- Anomaly criteria
- Assessment of fitness for purpose
- Reporting requirements

Each of these elements of the inspection strategy are discussed separately in later portions of this section.

It is important to allow for some flexibility in setting of the inspection strategy, and it should not be rigidly focused only on the results of the assessment work. It is prudent to always plan for surprises, thus the inspection strategy should allow for some inspection to be carried out on areas that are not anticipated to be a problem or if a sudden opportunity to inspect occurs. This is necessary because assessments are often made on the basis of incomplete information and an inaccurate understanding of true plant condition. Defects observed in equipment expected to be in good condition, or information from outside sources and safety alerts will highlight gaps in knowledge and will necessitate more data gathering and a reconsideration of the risk assessment on which the inspection strategy is based.

Inspection Methodology

It is necessary to define the nature of the inspection that is required. A wide range of inspection techniques are available, and the person setting the inspection strategy should specify the techniques that are most effective for the type of in-service deterioration predicted. In addition to in-service deterioration, inspection techniques may also need to detect fabrication defects if there is a chance of these remaining in equipment entering service. The likelihood of this can be assessed by review of the extent and validity of inspection carried out during fabrication and construction.

The nature of the required inspection should be considered in terms of:

- Reporting level (the required minimum deterioration to be reported)
- Effectiveness (capability of the inspection to detect and size the minimum reportable deterioration)

- Reliability (the probability of detection and sizing accuracy)
- Repeatability (for comparison with previous results)

Reporting levels should relate to fitness-for-service criteria. These criteria should be based on the tolerance of the component to deterioration, the possible deterioration rate, and the interval to be set until the next inspection. A comfortable margin should exist between the reporting level and any defects that are of concern in order to allow for uncertainties in the data.

The effectiveness of inspection techniques and procedures depends on the objectives of the inspection (e.g., detection or sizing) and the characteristics of potential defects. These characteristics include the defect type, size, position, and orientation. The person setting the inspection strategy should review the likely effectiveness of the inspection proposed for each site, particularly where there is complex weld geometry, poor surface finish, or restricted access.

Advances in NDE techniques have made it possible to determine material integrity remotely without direct access to the material under test. Nondestructive examination can be carried out through paint, coatings, or insulation and material can be tested that is at a long range from the access point. The advantage of these techniques is that internal surfaces of pressure vessels and tanks can be examined from the external surface. There are advantages for health and safety in such noninvasive inspection when this can be carried out effectively and reliably. These include a reduction of risks to personnel entering confined spaces. Noninvasive inspection can also make invasive inspection more efficient and effective by targeting the most suspect areas in advance, thereby making more efficient use of internal inspection time.

Other factors influencing the decision to inspect noninvasively include the susceptibility of the materials of construction to exposure to the atmosphere (for example, process equipment that is subject to a sour operating environment i.e., hydrogen sulfide, H_2S , bearing, may become susceptible to polythionic acid attack as a consequence of the interaction of sulfur and/or sulfide scales with atmospheric oxygen when exposed to the atmosphere during an invasive inspection), the availability of favorable invasive historical inspection data, and the relative costs associated with invasive and noninvasive inspection. Some techniques for noninvasive inspection are relatively new, therefore, the person setting the inspection requirement needs to consider whether there is sufficient confidence in the technique's capability and coverage for each application.

Any job-specific training requirements should also be considered. This issue has particular relevance to noninvasive inspection as specialized techniques not covered by standard certification schemes may be required.

General Preparation for Inspection

Prior to commencing the work, the person undertaking the inspection should:

- Become familiar with the work scope, including anomaly reporting limits and applicable procedures/routines, and liaising with support staff if clarification is sought
- Review the history of the item to be inspected, noting any previous anomalies/repairs/uninspected areas
- Note design and operating pressures and temperatures and likely corrosion mechanisms
- Review vessel drawings for details and process drawings for process familiarization.
- Make an initial site visit in order to arrange preparation for the inspection
- Ensure preparations are made for any access, dismantling, delagging, or cleaning requirements together with that for a permit to work
- Ensure that all items are cleaned and prepared to the degree required to enable all expected defects to be detected, giving due regard to the inspection technique to be used

Invasive versus Noninvasive Inspection

The safe operation of equipment subject to degradation in service depends, among other factors, on inspection by which the degradation can be detected before it becomes a threat to integrity. This has traditionally been achieved through visually inspecting the vessel interior by opening up and entering the vessel at prescribed intervals. This approach to inspection has a number of drawbacks, particularly in terms of the safety and environmental hazards posed by opening and entering vessels, and the cost of lost production during shutdown. As a result, inspections by noninvasive methods that require access to the vessel exterior only, are increasingly being considered as a realistic alternative. In considering noninvasive inspection, decisions need to be made to:

- Determine when noninvasive inspection can be applied
- Define the requirements for the techniques to be used
- Select techniques that meet the requirements of the inspection

The primary aim of the decision-making process is to determine whether noninvasive inspection will be capable of offering similar or better control over the probability of failure than would be achieved by internal visual inspection (Ref 10, 11).

Internal Visual Inspection

The traditional inspection method for most vessels has been to take them out of service, drain and clean them to an acceptable visual standard, and then inspect internally, relying mainly on

visual inspection by a competent inspector, supported by one or two appropriate NDE techniques. The primary concern when employing internal invasive inspection is ensuring the safety of the inspector by ensuring a nontoxic-atmosphere in the confined space. Nonetheless, invasive inspection is still widely used, but the difficulties associated with it have accelerated the development of noninvasive inspection techniques.

Conditions Favorable to Internal Visual Inspection:

- Potential degradation mechanisms and rate are not well understood.
- Sites of worst degradation are not easily predicted.
- Different areas may have different degradation mechanisms.
- Depth sizing of cracklike defects is not needed.
- Degradation is of a type that will be visible on exposed surfaces.
- Interior is readily accessed.
- Cost of shutdown is low or shutdown is required anyway for another purpose (e.g., for cleaning or repair).
- Acceptable health/safety/environmental risk is associated with vessel entry.
- Defects or damage expected in regions are not easily covered by noninvasive inspection.
- Exterior access is not straightforward.

Benefits of Internal Visual Inspection:

- Large-scale coverage rapidly achieved
- Lower cost of inspection activity itself
- Confidence based on extensive history of use

Limitations of Internal Visual Inspection:

- Subsurface defects cannot be identified, e.g., laminations, hydrogen damage, etc.
- Data are not readily quantified due to limitations on what can be measured.
- Data are not readily stored in a way that makes for direct comparison with past or future inspections.
- Requirement for internal cleaning
- Internal fittings may make access difficult.
- Internal coatings can be damaged while accessing the internal surfaces.
- Cannot be done through coating (although the coating itself can be examined)

Noninvasive Inspection

Noninvasive inspection techniques make it possible to test material for corrosion or defects on the opposite surface to where there is access. These techniques have the advantage that they avoid the need to enter the equipment for internal examination. For pressure vessels and tanks there is a reduction of risks to personnel entering confined spaces for inspection. Noninvasive inspection can also assist in helping to target the

most suspect areas in advance of invasive techniques.

Methods for noninvasive inspection are relatively new and therefore operators need to demonstrate sufficient confidence in the NDE technique capability and coverage for each application. Other factors influencing the decision to inspect using a noninvasive technique include the susceptibility of the materials of construction to the consequent exposure to the atmosphere when undertaking an invasive inspection, the availability of favorable historical inspection data, and the relative costs associated with invasive and noninvasive inspection.

Conditions Favorable to Noninvasive Inspection:

- All potential degradation mechanisms are well understood—i.e., knowing what to look for.
- Sites of worst degradation are readily predicted—i.e., knowing where to look.
- Degradation is not restricted to surface.
- Exterior access exists.
- Interior of vessel is not readily accessible (e.g., tube bundles).
- Cost of shutdown is high.
- Significant health/safety/environmental risk is associated with vessel entry.

Benefits of Noninvasive Inspection:

- There is reduced risk to inspectors.
- Environmental implications of opening vessels is avoided.
- It can often be done on line, thus avoiding the likely production loss associated with vessel shutdown.
- Accurate sizing of defects is often possible.
- Data can be quantified and recorded for future comparisons.
- Inspections can be carried out more frequently, particularly where process conditions are changing and/or highly variable.

Limitations of Noninvasive Inspection:

- Cost of inspection may be perceived as being high.
- Inspection may be time-consuming.
- No single inspection technique is applicable across all potential defect types.
- Limited confidence/awareness of newer techniques.
- Some areas may still be difficult to inspect reliably without direct access, e.g., vessel nozzles with reinforcement plates and flange faces on vessel nozzles.

Inspection Execution

All parts of a pressure vessel should be inspected in a systematic and detailed manner (subject to the scope of the applicable written scheme of inspection and any applicable code or standard), and any observed defects are to be measured and recorded. The inspection will

normally consist of a close visual inspection together with NDE of selected areas. The NDE techniques that are selected for use (together with any used in order to further inspect visually suspect areas) should be chosen to be compatible with both the material and likely form of defect to be encountered. All NDE activities should be covered by a written procedure. Where novel or nonstandard NDE techniques are being considered for use, the accompanying procedures and acceptance standards should be reviewed and endorsed by a competent person.

External Inspection. The following should be checked as appropriate:

- Drawings accurately show the actual vessel details; where deficiencies are observed, these should be made good in order to reflect the as-built status
- Vertical vessels are actually vertical and that skirt drains and cooling vents are clear
- The condition of supporting elements and load-carrying beams, tie down bolts, and sliding feet
- General condition of coatings
- Condition of shell barrels, heads, cones, nozzles, and associated welds for signs of distress, corrosion, or cracking. Any deformation present shall be measured.
- Earthing/(grounding) arrangements
- Manway closure supporting davits
- Vessel access stairs and platforms, associated bolting, and safety chains/bars
- Floor plates, ladder rungs, and steps are not worn or corroded; safety hoops are in place and intact.
- Data/nameplate details correct. It is also recommended that the safe working pressure is clearly marked and visible from instrumentation gages.
- Vessel tag or other identifying numbers are clearly stenciled on the vessel
- Details of pressure safety valves (PSVs) and bursting disks and test/installation setting details are correct, where recorded
- PSV general condition. If the PSV vents directly to the atmosphere, ensure the vent pipe has a small drain hole in it to prevent water and debris buildup.
- Condition and cleanliness of any flame-arresting devices
- Suitability and condition of any screwed fittings/plugs and vessel penetration threads
- Condition of any fireproofing
- External brackets, support saddles, doubler plates, and other shell attachments, together with associated welds are intact with no signs of distress
- Condition of insulation supports, wind girders, and stiffening rings
- Nozzles and flanged connections shall be examined for signs of distortion, leaks, and loose/corroded bolting. Exposed flange faces and nozzles shall be examined for corrosion and other damage.
- Adequacy of support for associated pipework—insulation kits fitted if required

- Insulation, cladding, and seal arrangements for indication of water ingress and the possibility of corrosion under insulation (CUI).
- General condition of vessel bridles, float pots, and floats. In addition, liaison with operations personnel is recommended in order to ascertain whether regular blow-down operations have been undertaken, otherwise dead-leg corrosion may have occurred.
- The condition of any other associated dead legs
- Evidence of the correct operation of automatic draining devices associated with the vessel

For pipe work inspections, the inspector should walk the line to be inspected from end to end and review isometric drawings to ensure they reflect the current site configuration, amending as required (including any additional access or delagging requirements). Particular attention should be paid to the presence of equipment items that may induce turbulent flow and potentially accelerate material loss within a pipe work system. Items of this type, such as process control valves, orifice plates, pump discharges, flow measurement devices, thermowells, and so forth, should be highlighted on the isometric drawings in order to assist in the preparation of future work scopes. Similar attention should also be paid to any areas of no- or low-flow conditions (so-called “dead legs”) where debris could settle out.

Internal Inspection

All areas of the vessel should be made available for inspection (subject to the scope of applicable written scheme of inspection). The vessel walls and nozzles should be cleared of debris so that a full visual inspection can be made. For vessels with irremovable close-packed internals, such as tube bundles, alternative inspection techniques may be required. Typical features to be examined for evidence of corrosion, erosion, mechanical damage, or cracking, if appropriate, are:

- Shell barrels, heads, cones, nozzles, and associated welds, looking for any signs of distress, corrosion, or cracking
- Debris found within the vessel prior to cleaning. This may include mechanical items from the vessel or upstream pipe work. Where appropriate, samples of deposit/sludge should be taken for analysis.
- Internal linings. Blisters in coatings should be investigated to confirm that they are in the coating and not in the parent material (possible hydrogen damage) and to ascertain the condition of the material surface beneath them.
- Any internal corrosion-monitoring features such as corrosion coupons or metallic lining tags
- Internal bladders or instrumentation floats
- Wear plates and impingement areas, together with any associated welds

- Attachments/welds to shell, brackets, foamers, weirs, baffles, diffusers, and vortex breakers (these being possible areas of high velocity and hence erosion, or fatigue/collapse due to hydrodynamic vortex breaking or blockage)
- Internal pipe work, including sand or desilting facilities and nozzles
- Sacrificial anodes—depletion, attachment, and bonding continuity
- Electrostatic dehydration arrangements, including the security of any internal cables
- Security, tightness, and general condition of bolting
- Other fittings such as demisters, vane packs, filter supports, etc.

Risk-Based Inspection

Risk-based inspection allows operators to manage the integrity of their plants by planning equipment inspection on the basis of information obtained from risk assessments. It is one of a range of measures within the wider process of plant integrity management. To use this approach, the operator needs to demonstrate that the risk assessment and inspection planning processes are being implemented in an effective and appropriate manner.

The risk-based approach requires that the quality and veracity of the information is tested and validated. Confidence in the assessment of risk is reduced when there is lack of, or uncertainty in, the key information required to assess integrity. Information on the integrity of plant can be generated from the design, operational experience, and inspection records, and from sound knowledge of the deterioration mechanisms and the rate at which deterioration will proceed. Inspections can then be planned at appropriate intervals using inspection methods that are able to detect the type and level of deterioration anticipated in order to facilitate the accurate assessment of pressure systems equipment integrity.

The recent arrival of goal-setting legislation and standards enables the planning of inspections to be based on the assessed risks, thus allowing a degree of flexibility when deciding on a suitable written scheme of inspection in terms of the equipment to be inspected and the frequency and nature of inspection. The information generated by the risk assessment is therefore the primary foundation on which to base these judgements, thus assuring a safe and suitable scheme that is not unduly restrictive.

The assessment of risk needs to take account of changes over time as equipment or plant conditions physically alter or because new information becomes available. Feedback of inspection results and the continuous reassessment of risk during the life of the plant is therefore a vital feature of an effective risk-based inspection scheme. Changes in contractors, if used, must be properly planned if this reassessment cycle is not to be disrupted.

Risk-based inspection is a logical and structured process of planning and evaluation. The process can be summarized in the following outline steps:

- Identify relevant items of equipment
- Identify potential degradation mechanisms
- Assess probability, consequences, and hence risk associated with such degradation
- Develop suitable inspection schemes (in conjunction with other mitigation measures) to detect and monitor this degradation, based on the assessed risk
- Execution of inspection, monitoring, and mitigation activities in accordance with the schemes
- Review, summary, and revision of the schemes to ensure they remain suitable and reassess inspection return time intervals

Depending on the level of data available and the extent of analysis undertaken, risk-based inspection approaches are generally classified as being qualitative, semiquantitative, or quantitative with an increasing degree of complexity. Risk-based inspection approaches have received a lot of attention in recent years, and various bodies have issued standards and guidelines regarding their application (Ref 12–15).

Inspection Techniques

A wide variety of techniques ranging from simple visual inspections through well-established methods such as radiography and ultrasonic testing to new and highly specialized methods are available for use. Some are identified subsequently. Not all the techniques are suitable for all materials, and the choice of techniques has to be carefully matched to a range of considerations such as material, geometry, access, temperature, light levels, and the type of flaw or degradation mechanism that the inspection is attempting to detect. Additional information on inspection techniques can be found in the Appendix to this article.

Typical defects that may be encountered are shown in Fig. 1. The figure shows a range of common surface and embedded defects within a pipe. External degradation, such as corrosion under insulation (CUI), fatigue cracking, and stress corrosion cracking (SCC), also may occur.

To maximize the likelihood of detecting and sizing defects and degradation, the most appropriate inspection techniques need to be matched to the individual defect types and orientations. Techniques can be generally separated into those for detecting and sizing surface defects and those for embedded defects; rarely is a technique suitable for all types of defects.

To select the most appropriate technique, it is necessary to specify the type of defect that is anticipated and what the selected technique needs to detect and size. The inspection specification needs to consider:

Fig. 1 Different forms of corrosion and deterioration. SCC, stress-corrosion cracking. SSC, sulfide stress cracking. HIC, hydrogen-induced cracking. Source: Ref 16

- The damage mechanism—location, type, morphology, and orientation
- Whether the defect is expected to be a surface-breaking or embedded defect
- The size of defect that needs to be detected and the sizing errors that can be tolerated

Where the nature of anticipated defects is not known, the defect description is then defined by the capabilities of the technique being applied. The plant item can be passed only as being clean of defects detectable by this technique. In such cases, a range of techniques would normally be specified based on past experience of their capabilities in detecting and sizing a range of defect types. Once the specification has been produced, the appropriate method(s) and technique(s) can then be selected. The specification should also address competency requirements for those undertaking the inspection.

Each inspection technique has advantages and disadvantages. Some of the important considerations in the selection of a suitable technique are:

- **Required access for inspection:** This will vary considerably depending on the technique and may limit the techniques that can be used in a particular situation.
- **Surface preparation:** The surface of the equipment to be tested is important because some techniques ideally require a bare metal surface, while others are more tolerant of paints and coatings.
- **Portability of equipment:** This may be an important consideration in relation to the installation of the equipment and to its handling (e.g., rope access).
- **User skill:** Different levels of training are appropriate to the various techniques with

some techniques requiring only a low skill level, while others require a high degree of knowledge. Use of a technique by inappropriately qualified personnel may result in erroneous results and the possibility of not detecting flaws that are present.

- **Competence:** Operators should be certified to Personnel Certification Scheme in Non-destructive Examination (PCN) or American Society of Nondestructive Testing (ASNT) standards or to an equivalent nationally recognized qualification program.
- **Site safety implications:** Some NDE techniques may introduce additional hazards to the site, such as electrical (spark potential), chemical, fire, or radiation. The implications of introducing an additional hazard to the site during the inspection should be addressed.
- **Robustness of NDE equipment:** This should cover both physical characteristics as well as electronic.
- **Coverage:** This is an important aspect of any NDE technique and describes the fraction of the plant that can be inspected by a particular method. It is important to consider the coverage to ensure that a representative area is examined and the likelihood of missing the detection of flaws has been minimized.
- **Speed:** The speed at which a technique can be carried out is an important parameter and will influence the cost of an inspection method for a specified required coverage.
- **Sensitivity:** The reliability of each technique to detect flaws of different types varies. It is important, therefore, that an appropriate technique is chosen to maximize the potential identification of flaws.

In selecting any NDE technique, it is important to bear in mind that no individual technique

can be expected to be 100% accurate in terms of detection and accurately sizing defects. In some circumstances, it may be necessary to combine techniques to achieve the required coverage and accurate sizing of defects.

Competence Assurance of Inspection Personnel

Competence is gained by inspectors satisfying requirements of qualification, training, and experience. It is not possible to become a competent inspector only by passing an exam or learning a new technique. It can be achieved only over a period of time exposed to the relevant operating plant. Some standards bodies, such as the American Petroleum Institute (API), organize courses and examinations that prospective inspectors must complete satisfactorily before they are allowed to perform inspection on particular pieces of equipment, and these are closely aligned to the inspection requirements of the relevant standards.

A plant inspector is now expected to have skills over and above the basic competence to perform an inspection to meet the requirements of the relevant code or standard. Increasingly, the inspector needs to be aware of plant conditions and how these conditions affect the deterioration of equipment because the inspector is expected to play a key role in ensuring that the inspection regime remains suitable for changing conditions as the plant ages. In addition to having the ability to carry out the inspection, the inspector is also expected to have some or all of the following skills and abilities:

- Classify equipment according to its inventory, service, and hazard
- Develop inspection strategies
- Conduct risk-based inspection assessments
- Develop written schemes of inspection
- Develop inspection work scopes
- Produce inspection procedures
- Produce inspection drawings/data sheets
- Produce inspection workbooks/workpacks
- Carry out safety-risk assessments
- Supervise NDE, approve results and anomaly reports
- Entry of results into an appropriate inspection database
- Assessment of results
- Anomaly assessments
- Fitness-for-purpose assessments
- Incident investigations
- Failure analysis
- Auditing

As such, inspectors are increasingly being expected to perform as engineering professionals, not just as checkers or verifiers. This change of status needs to be reflected in the level of competence assurance and an appropriate code or standard is needed that covers the full range of activities expected of the modern-day inspector. To date, no single code or standard covers all areas.

The mainstream nondestructive inspection techniques such as ultrasonics, radiography, and the basic surface crack detection techniques are covered by national and international standards for the testing and certification of practitioners. These qualifications are recognized throughout industry and should be seen as the minimum requirement for assessing the competence of an NDE technician. This basic ability in the technique needs to be backed up by relevant experience of applying the technique, preferably in conditions that closely replicate those required in the field.

Ultrasonic inspection programs are often designed on the basis of national or international standards such as BS EN 1714 (Ref 17). The inspection procedure often determines the approach to be taken in terms of the details specified in the standards for beam angles, scanning patterns, inspection sensitivities, probe types, and so forth, and often the detail of the defect types the inspection is intended to detect are ignored.

International standards such as BS EN 473 (Ref 18) define the training and qualification requirements for inspection personnel using the techniques specified. Often a written examination and a practical test that requires defects to be identified is required. Such testing is limited in scope, and only a small number of defects can normally be assessed. This leads to difficulties in later inspections where operators may not be directly qualified for the detection and measurement of defects that are thought to be present and for which the inspection is specifically being targeted. In order to overcome this difficulty, a number of levels of competence have been defined. Ultrasonic testing (UT) level 3, for example, requires demonstrating a more detailed level of understanding of the fundamentals of a particular inspection method than either level 1 or level 2 operators. However, the key issue is that the training and qualifications must be appropriate to a particular inspection if potential problems are to be avoided.

The Programme for the Assessment of NDT in Industry (PANI) identified a number of areas that need to be addressed in the development of any inspection regime (Ref 19). It identified the circumstances under which an approach to inspection based simply on the use of standards and national certification schemes may be inadequate.

Inspection Coverage

The amount of inspection carried out during manufacture depends on the class and design code of the vessel or component. In-service inspection should take this into account when deciding the amount of vessel or component to inspect. Frequently a sample of, say, 10% of all welds are inspected. Justification that this will provide the required confidence level in the integrity of the vessel should be provided (e.g., evidence that inspection is targeted at areas

where defects are known to initiate). Higher-risk vessels would require a greater coverage, based on an assessment of the risks involved.

When setting the inspection requirements, the threats to integrity of each item of equipment are likely to be either uniformly distributed (such as general corrosion) or localized to specific areas. There may be a decreasing return on inspection in terms of risk reduction if a particular mechanism is shown to be absent or, conversely, if there is widespread attack. This is particularly relevant to decisions of whether invasive or noninvasive inspections are most suitable for a particular item.

Sites that may be susceptible to deterioration or failure (such as welds, high-stress regions, penetrations, saddle points, exposed surfaces, and liquid level interfaces) should be identified in the written scheme of examination. The inspection scheme should also take account of likely sites highlighted from the earlier review of preexisting defects or repairs from the construction records.

For a material/component where the degradation or defect distribution is uniform, the inspection effectiveness is given by the probability of detection for the technique multiplied by the percentage area covered. In practice, defect distributions will often not be uniform and different regions will tend to have different degradation rates. Under these conditions, the inspection effectiveness is determined not only by the percentage area covered but also by how the defects in the area covered relate to the overall defect population. If the inspection is carried out in an area where the majority of the worst defects are likely to occur, then a high effectiveness is possible even though the actual area inspected may be small. Conversely, a large area may be inspected. However, if this does not encompass the region where the worst defects are located, the effectiveness would be low.

Specification of adequate coverage is particularly important in piping systems because these are seldom inspected over 100% of their surface. Selection of suitable coverage needs to take account of the issues as described previously, particularly addressing those locations where enhanced degradation might be expected at areas of turbulence or stagnant conditions. Some knowledge of process conditions and flow patterns is therefore required before an appropriate coverage can be defined.

Traditionally, internal visual inspection will be applied with a significant proportion of the

accessible interior of the vessel being inspected. Given the preceding considerations, the effectiveness can be matched using noninvasive inspection with a lesser overall coverage provided it is directed at the regions of worst defects. This can be achieved only when the regions of worst defects can be predicted. A key consideration in defining the coverage requirements for noninvasive inspection is therefore the confidence in the ability to predict the sites of worst degradation.

Inspection Periodicity

Traditionally, inspection of pressure vessels has been assigned on a set return period. With the introduction of risk-based inspection, the interval between inspections can change. It is often the case, subsequent to the formal evaluation of risk, that inspection intervals can be increased. However, should a high-risk component be identified, the periodicity may require to be reduced. Risk-based inspection is intended to define the optimal inspection periodicities based on predefined risk acceptance criteria; it is not intended to be used as a wholesale means of cutting inspection costs by unjustifiably extending inspection periods. Significant increases in the time between inspections should have a sound technical justification.

Established practice is to use one or more of the following approaches as a basis to set the maximum intervals between inspections:

- Historical experience for the specific type of equipment (e.g., boilers, air receivers)
- Industry guidelines for classes of equipment based on in-service experience
- As a prescribed percentage of the estimated residual life or the design life

A common approach is based on the setting of inspection grades for particular classes of equipment (Ref 20, 21). The allocation of grades is based on an assessment of actual or predicted deterioration. If deterioration is expected at a relatively rapid rate or there is little evidence or knowledge of the operational effects, the equipment is allocated a low grade, i.e., representing a high risk of failure and a shorter inspection period. If deterioration is at a reasonable and predictable rate, a higher grading is assigned with a correspondingly longer inspection period. An example of the type of matrix used is shown in Table 1.

Typically, maximum examination intervals between 2 and 12 years are recommended

Table 1 Varying inspection intervals based on component criticality and grading principles

Criticality rating	Inspection period (months)				Maximum review periods
	Grade 0	Grade 1	Grade 2	Grade 3	
1 High risk	24	36	N/A	N/A	12 months
2	24	48	N/A	N/A	24 months
3	36	48	72	96	48 months
4	36	48	84	120	60 months
5 Low risk	36	60	96	144	72 months

Source: Ref 22

depending on the type of equipment and the assessed grade. New equipment would normally be assigned grade 0 unless relevant operating history was available for equivalent equipment in the same service. Successive examination intervals can be extended (or reduced) if the grade of the equipment and/or the overall risk profile is changed. This may happen following examinations where favorable (or unfavorable) operating experience of the equipment, or "identical" plant on similar duty, is observed. This approach is most frequently adopted where qualitative methods have been used to devise risk matrices.

When an inspection period has been set, it is good practice to periodically review the risk assessment to ensure that it is still valid and that the assigned inspection period is still appropriate (Table 1). This review would include assessment of any significant change in operating conditions and any impact they might have on corrosion rate and, therefore, on required inspection frequency. The setting of the review period can be done on the basis of a fixed time period (e.g., set percentage of inspection period) or when a key process variable exceeds a previously established threshold level. This ensures that the inspection regime can be kept relevant, rather than just waiting for the next set of inspection results to trigger an update.

When applying industry guidelines, the extent of operating experience is a key factor to be considered. Appropriate margins are necessary to allow for uncertainties and the reliability and relevance of the supporting data for the existence, rate, and form of deterioration.

The remaining life approach to determining inspection intervals is based on calculating the remaining life of the equipment based on its tolerance to deterioration, defects, or damage and the rate of deterioration. The tolerance to deterioration is determined by assessing fitness-for-service at future times according to the deterioration predicted using documented methods (Ref 12, 23).

An inspection interval can then be prescribed as a percentage of the remaining life. The percentage selected needs to take uncertainties and reliability of the data into account. As a guide, API 510 (Ref 3) and 570 (Ref 4) state that the maximum interval between inspections should not exceed 50% of the estimated remaining life based on the measured corrosion rate ("half-life" rule). This approach can be used as a rough guide when used in conjunction with the Institute of Petroleum (IP) 12/13 approach and backed up by a robust inspection scheme focused on locations of shortest predicted remaining life, dependent on the service conditions.

The assessment of remaining life needs to take all known and potential deterioration mechanisms into account. Calculations should be based on conservative assumptions and contain adequate margins to allow for uncertainties. The reliability of the available inspection and materials data is a key consideration in assessing the current condition of the equipment,

the rate of deterioration, and the continued fitness-for-service.

Some deterioration mechanisms (e.g., fatigue crack growth and SCC) do not proceed at a constant rate but vary with time or initiate late in life. The remaining life calculation is then no longer a simple ratio of deterioration tolerance to deterioration rate. In these cases, a fixed interval based on a fraction of the remaining life may not be appropriate, and there may be a need for more frequent inspection toward the end of predicted life. In some cases, such as SCC, first appearance of defects may be sufficient justification to withdraw the unit from service. This leads to the need to have in place a clear definition of anomaly criteria.

Inspection Anomaly Criteria

As part of the planning of the inspection activities, appropriate anomaly criteria should be set. All anomalies highlighted by the inspection should be assessed against acceptance criteria for their impact on pressure system integrity. The initial assessment is likely to be carried out by the inspector or technician carrying out the inspection, and this will be very much at a broad level to determine whether there is an immediate need for action. For example, if the defect is obviously serious, immediate shutdown of the component or system may be required. Where an appropriate inspection scheme has been in place, it is anticipated that such occurrences should be extremely rare.

More commonly, the inspector will, as part of his reporting of the inspection, be expected to categorize potential anomalies against the acceptance criteria set for the inspection. In most cases, acceptance criteria will be as detailed in the original design code or specification. In the case of wall thickness measurements, these are well established. For example, the measured wall thickness can be compared with minimum allowable wall thickness (MAWT) as calculated in accordance with the design code. Dependent on service conditions and project practice, it is normal practice to specify a number of criteria of nonconformity that will progressively flag an increasing extent of deterioration. For wall thickness, a first flag would be raised when the measured wall thickness is less than the nominal wall thickness minus the manufacturer's tolerance minus the corrosion allowance. This is generally well above the calculated MAWT. It allows the inspection period to be reviewed to determine whether there is a need to inspect more frequently and to ensure that further deterioration can be detected before MAWT is reached. A second flag is typically set a certain amount above the MAWT. Dependent on the criticality of service and the anticipated rate of deterioration, this is often around 1 mm (0.04 in.) above MAWT (with an absolute minimum remaining thickness of 3 mm, or 0.12 in., for carbon steel pipe work from the viewpoint of mechanical strength rather than purely pressure retention).

This flag gives a certain margin for allowing time to plan for replacement or other mitigation measure.

As just outlined, acceptance criteria related to wall thickness are well established and understood, particularly with reference to design codes. However, particular care should be taken when a localized wall loss is identified, e.g., internal pitting. In such circumstances, individual thinned areas can be acceptable below the overall MAWT, subject to detailed assessment by a competent person. In such cases, consideration should be given to extending the areas to be examined to ensure that the areas of maximum thinning have been detected.

Unlike wall thinning, which normally can be tolerated and monitored within established limits, cracking is seldom acceptable within a pressure system. In most cases, detection of cracking will be highlighted as a serious anomaly that requires urgent action in terms of planned shutdown and replacement of the item. However, certain types of cracking may be acceptable to continue in service for a period, subject to regular monitoring. Such circumstances should be assessed by a competent person. It is particularly important to identify the cause of the cracking. For example, detection of fatigue cracks may highlight an operational problem that can be resolved and that will remove the excitation from the component and thereby prevent further fatigue. The crack may then be left in service, subject to engineering assessment and an appropriate monitoring program. However, other modes of cracking can be more rapid and unpredictable and any instance of these modes (e.g., SCC) will nearly always require prompt replacement of the item unless the process can be altered to prevent further deterioration and the cracking can be confidently monitored. Such decisions need to be taken into consideration by a competent person in consultation with relevant specialists on materials, corrosion, and NDE.

Assessment of Fitness for Purpose

Following an inspection, it is important that the results of the inspection are analyzed and that the fitness for purpose of the equipment is then assessed. It is important to take into account the accuracy associated in the measurements determined by the NDE technique chosen and the possible implications of inaccuracies on the fitness for purpose assessment. For example, areas of extensive pitting may be detected and measurements made. However, it may not be possible to guarantee that the most severe pits have been found. Under these circumstances, it may be necessary to allow for the possibility of more serious pitting being present (e.g., by using mathematical models).

Reporting Requirements

The reporting requirements should be established in the written scheme of inspection and/or

supporting procedures. Normally, reports will be made on preformatted inspection report templates, which ensures a common reporting standard and that all relevant data are recorded.

Specific reporting requirements will depend on the legislative regime, relevant codes, and any plant-specific requirements. In general, it is suggested that an inspection report should clearly state:

- Identification of the document, i.e., date of issue and unique identification
- Identification of the issuing body
- Identification of the client
- Description of the inspection work ordered
- Identification of the object(s) inspected and, where applicable, identification of the specific components that have been inspected and identification of locations where NDE methods have been applied
- Information on what has been omitted if the assignment was not carried out in full
- Identification or brief description of the inspection method(s) and procedure(s) used, mentioning the deviations from, additions to, or exclusions from the agreed methods and procedures
- If relevant, specification of inspection equipment used
- Where applicable, and if not stated in the inspection method or procedure, reference to or description of the sampling method and information on where, when, how, and by whom the samples were taken
- If part of the inspection work has been subcontracted, identification of this part and relevant information on the subcontractor
- Information on where and when the inspection was carried out
- Environmental conditions during the inspection, if relevant
- The results of the inspection, including a declaration of conformity and any defects or other noncompliances found (results can be supported by tables, graphs, sketches, and photographs)
- Any repairs needed and the time scale for completion
- Any changes in the safe operating limits and the date by which they should be made
- Any change in the written scheme of examination
- Date by which the next examination must be completed
- Other relevant information, e.g., conditions for publication of the report, advice, and recommendations
- The inspector's mark or seal
- Names and job titles of the staff members who have performed the inspection and of the person assuming responsibility for the inspection and their signatures

All reports of inspections are to be compiled as soon as possible after the inspection has been completed. Certain legislation states a maximum period (commonly, 28 days), which should be complied with where it applies. In many cases,

a parallel system for immediate reporting of high-priority safety critical concerns raised by inspectors runs alongside the more routine inspection reporting system.

Data Collection and Management

Reliable data are essential for any effective integrity management system. This has always been the case but is even more true now that decisions regarding inspection are being made on the basis of an assessment of risk. It is now even more important that all data are documented so that the basis for decisions can be justified and the true plant condition can be accurately assessed and realistic assessments of future service life made.

With the development of noninvasive inspection methods, the volume of data generated electronically by these methods can be orders of magnitude greater than that produced by more conventional methods, and it is important that these data are efficiently recorded and analyzed. Equally, there is no value in generating huge streams of data if they are not reviewed, assessed, and used to provide trending information. This information can then be used to set future inspection periods and can be fed back to the operator in terms of the condition of the plant measured against the predicted condition.

Prior to first entering service, each plant component will have a history or record that could be of use to the inspector in the future assessment of its condition. A lot of this useful information is not retained and is effectively lost in terms of applying it in future assessments. If a component is designed and manufactured with future inspection requirements in mind, then an extensive pack of data will be available. In many cases this is required for legislative reasons or to comply with standards. However, the production of this pack of data is often seen as little more than a contractual obligation so it is put together at the fabrication stage, often consigned to archive. Ideally, the data pack from fabrication should become the property of the inspection function with the responsibility for updating any changes, upgrades, or modifications, and also recording any significant plant events, upsets, or failures.

The following should be considered as the minimum level of data required to properly register an item:

- For vessels, general arrangement and detail drawings; for pipework, process and instrumentation diagram, or drawing, (P&ID) and construction isometrics
- Fabrication release documentation including welding logs, NDE reports, hydrotest certificates, defects/repairs, and vendor surveillance release certification
- Vessel data sheet or alternative record of relevant design, fabrication, and operating criteria

- Details of any additional site designated identification number
- Details from vessel data book for American Society of Mechanical Engineers (ASME) or BS PD5500 vessels
- Related purchase order number (for traceability of related documents)
- Initial inspection report from fabrication yard or site precommissioning
- A statement from the competent person with regard to the fitness-for-service evaluation and reference to applicable written scheme of examination
- Records of inclusion into the site database
- Any applicable correspondence, particularly related to any concessions or agreed changes to specification.

These data and all subsequent inspection reports should be held in a designated equipment file, which may be electronic or hard copy (paper) record.

Once an item has been registered, a fitness-for-purpose assessment or similar risk assessment will be carried out to determine, among other things, the requirements for periodic inspection of the component. This evaluation will be made on the basis of an assumption of the plant operating and environmental conditions to which the component will be exposed during its service life. Service conditions can vary over the life of plant, so it is important that this service and environmental data are regularly updated so that any required changes can be made to the inspection regime to account for any impact of condition changes on the continued fitness for service of the component. To this end, a mechanism should be put in place to ensure that all relevant data are updated and communicated to those responsible for setting the inspection regime. Similarly, a mechanism is needed to ensure feedback from the inspection results to the plant operators so that they are kept informed of the current condition of their plant.

Data Acquisition

Traditionally, inspection data were collected and recorded manually; i.e., the inspector carried out the inspection, made notes of his or her observations, recorded wall thickness readings, and presented the whole in a paper report. With more recent developments of portable electronic equipment and advanced inspection techniques, this situation is now substantially changed.

As part of the inspection workpack, the inspector is now likely to have a set of electronic recording templates that can be accessed on a portable computer or palmtop electronic notebook, allowing the inspector to directly input findings and readings. This information can be backed up with digital photographs that can be stored for comparison with images from previous and future inspections. Advanced NDE techniques produce a great amount of data, particularly scanning techniques, which can also be

recorded electronically for subsequent processing and review.

All of these data need to be effectively managed if the inspection data are to be converted into reliable knowledge of plant condition. One commonly adopted approach is to establish a plant database, which contains data relevant to the design, operation, and maintenance of the plant components but also stores inspection data and reports. A well-structured and maintained database can be a valuable tool in managing the integrity of an asset by enabling the operator to view all relevant data in summary form as well as view realistic trends for past and projected future performance. However, a poorly constructed or poorly maintained database is effectively worthless because it cannot be relied upon to give a realistic view of plant condition and may even be potentially dangerous if it misleads optimistically.

A suitable hierarchy should be established for the database. This should be established on a logical basis to ensure that data are held correctly and can also be related to relevant features on the same system. A simple hierarchy could be:

1. Plant name, e.g., terminal or platform name or designator
2. Location/area, e.g., module or plant number
3. System, e.g., service such as oil, gas, steam, etc.
4. Component, e.g., vessel, pipe, heat exchanger, etc., and unique component number
5. Feature, e.g., elbow, weld, nozzle, and unique feature number
6. Keypoint, e.g., location and orientation details

Each heading could then be broken down into subheadings. For example, feature could have properties such as material type, dimensions, orientation, and so forth. These would be recorded to create a unique record definition for each feature. Data could then be assigned at the appropriate level of detail. For example, process data such as stream composition or flow rate could be input at system level, vessel visual inspection reports at component level, repair/modification details at feature level, and individual wall thickness readings at keypoint level. By appropriately linking the various items to their parent component or system, all data could be held at the correct level and called on as required for review at overview or detailed level. Additionally, once in a suitably structured database, inspection data are then available for linkage to other systems such as to update plant maintenance databases.

Reporting and Trending

To maximize the value of information obtained from inspections, it is important that the results are presented in a comprehensive and logical manner that allows the current status to be grasped immediately without losing any of the level of detail that might subsequently be used

to give deeper understanding of plant condition and trends.

As already mentioned it is important to have a system in place for the recording and storage of inspection reports and data, either as paper records or in an electronic database. In addition to providing the historic record of plant condition, this data can be used to establish trends and to provide predictions of future plant performance and deterioration.

One traditional method of trending has been to use a series of keypoints, i.e., set positions on vessels and pipe work that are inspected using the same technique over a period of years. By recording the wall thickness at each of these keypoints over a period, trends can be established by plotting the wall thickness against time. Typically, an overall rate is quoted, which is the rate of deterioration over the period between the first reading and the most recent reading for a particular keypoint. Sometimes, a short-term corrosion rate is quoted, which is the rate over the two most recent readings at a particular keypoint. This value is sometimes quoted as being more relevant to current rather than historical plant conditions. However, this whole approach has a number of significant drawbacks:

- It reflects data only from comparatively few points in the system.
- It does not take account of the likely deterioration mechanism(s).
- Straight-line trending is crude and not necessarily correct.
- Errors in the inspection are not considered and are often found only when subsequent readings do not fit the line established from previous spurious data.
- It provides a restricted sampling percentage.

The keypoint approach is still commonly in use but needs to be backed up within an inspection strategy that is based on an understanding of likely deterioration mechanisms, use of inspection techniques that cover larger areas, and with a more advanced statistical approach to the data produced. Rather than extrapolating a simple straight line between two readings, the significance of the readings needs to be taken into account by considering a greater population of readings. It is also important that any inherent error in wall thickness readings (perhaps ± 0.5 mm, or 0.02 in.) needs to be considered in any extrapolation of deterioration rate for setting of future inspection frequency or consideration of likely remaining service life.

Any inspection data and the rates and predictions made from them should be compared with the predictions of deterioration made at the risk-assessment stage when setting the inspection strategy. If the measured rate is at variance with these predictions, it is likely that the inspection strategy will need to be amended. In this way, the inspection strategy can be kept relevant to the actual plant condition.

Where a risk-based approach has been used in setting inspection requirements, it is important that a logical approach be taken to sample

inspection, particularly in the definition of appropriate inspection locations and number of readings that constitute a realistic sample. Such decisions need to be appropriate to the assessed level of risk and need to consider the level of understanding of the likely deterioration mechanisms. This is related to the earlier comment on sample inspections and risk-based inspection. If random pitting corrosion is the likely deterioration mechanism, an inspection regime based on a few keypoint measurements of wall thickness is unlikely to detect the worst pit, and any trends derived from such data would be misleading. However, where corrosion is known to be essentially uniform, a few keypoint readings may prove adequate to establish data for realistic trending.

Where nonuniform forms of corrosion such as pitting are encountered, advanced statistical techniques can be employed to consider the effectiveness of the inspection coverage in terms of its likelihood of detecting the deepest pit in a population. Work by Kowaka (Ref 24) has categorized different statistical distributions for a range of corrosion types. For example, pit depth in a carbon steel freshwater supply pipe was shown to follow a normal (or Gaussian) distribution, whereas the maximum pit depth for a petroleum tank bottom plate was shown to be described by an extreme value (type 1) distribution. Such generalizations need to be treated with caution, and the specific data for each inspection need to be analyzed before any assumptions on distribution or trending can be made. Further references on the use of probabilities and statistics in the interpretation and trending of inspection data are included at the end of this article.

Review and Audit

Having planned, carried out, reported, and assessed the results of an inspection program, the cycle will begin again. It is essential that the whole cycle be subject to regular review to ensure that the aims of the inspection are being met. This is not simply an examination of adherence to specific procedures (i.e., performance monitoring). The reviews should encompass all facets of the cycle and answer such questions as:

- Is the inspection policy still valid?
- Has the inspection planning strategy taken note of new techniques of inspection?
- Have causes of failure been identified and acted on in future planning?
- Have process or plant changes been alerted to the inspection planning function?

It is important that audit and review findings be communicated to all concerned, and identified changes or recommendations are actioned. Changes in contractors or reorganizations should not impede or delay the process of continual review.

Appendix: Review of Inspection Techniques

Some in-service inspection techniques have been mentioned previously. These are now addressed in more detail, outlining their capabilities and limitations. Note that some of these and other techniques are covered in much more depth and detail in *Nondestructive Evaluation and Quality Control*, Vol 17 (Ref 25), and in *Corrosion Fundamentals, Testing, and Protection*, Vol 13A, of the *ASM Handbook*.

It is important that any inspection activity is planned carefully and that those carrying out the inspection are competent and have sufficient information and support facilities for a successful inspection. This is particularly important where the inspection activity is carried out by another body. This is now often the case, particularly as many plant operators no longer have their own in-house independent inspection function. It is also likely that for some of the more specialized techniques, another company might be used for that part of the inspection. Thus, there may be several interfaces, between the plant operator, the inspection company, and the specialist inspection contractor. In such cases, the potential for communication problems is clear, and this process needs to be managed effectively to ensure completion of a safe, worthwhile inspection that gives relevant and realistic data that can be relied on by the plant operator in setting future operating and inspection schemes.

Visual Inspection

Visual inspection is still the bedrock of most inspection regimes. In addition to traditional thorough inspection by the naked eye, visual inspection can be assisted by such optical aids as magnifying glasses or borescopes. More recently, some visual inspections have been carried out remotely using a mechanized probe inserted into the component being inspected, with the inspector viewing the image remotely outside the component. In such cases, care needs to be taken to ensure that sufficient coverage is achieved and that the image is of sufficient quality and depth to ensure that the required inspection standard can be achieved.

Concerns for the health and safety of personnel entering confined spaces for cleaning and for inspection are likely to provide a further driver for more remote inspection techniques. While the concern for health and safety must be paramount, the inspection undertaken must be as thorough as possible, using the most relevant and reliable techniques.

Ultrasonic Inspection

Conventional Ultrasonic Inspection. Ultrasonic (high-frequency sound) inspection is the

workhorse of in-service NDE, being used to give measurements of remaining wall thickness at discrete test points or over a scanned area. It can also be used to detect and size defects such as cracks, voids, and inclusions.

Ultrasonic techniques use high-frequency sound waves that are reflected from interfaces or discontinuities, having large acoustic impedance values. In thickness checking, the reflections from the wall surfaces are measured. In defect detection, reflections from cracks, voids, inclusions, or other discontinuities are detected. The transfer of sound from the ultrasonic probe to the component requires a coupling medium to match the acoustic impedance between the inspection probe and the component being examined. The condition of the interface determines how much sound is transferred into the component, how much is scattered, and how much background noise is produced so a certain standard of surface finish is required to allow ultrasonics to be used reliably. For example, the surface should be clean and free of extensive corrosion products. Ideally, surface coatings should be removed for critical applications, but this is seldom done in practice. Instead an allowance is made for the coating thickness in the measured value of remaining wall thickness. Alternatively, an appropriate ultrasonic inspection procedure can be applied that eliminates the thickness of the coating from the recorded measurement.

When used over large areas, ultrasonic measuring is generally carried out on a sample basis, for example, the thinnest point in a scaled grid being quoted as representative of that area. Where full coverage of large areas is required, semiautomated or automated ultrasonic scanning techniques have been developed that ensure full coverage and that allow large amounts of data to be recorded. Automated techniques do not do away with the need for qualified technicians; where automated techniques are used, the technicians can concentrate more on the quality of data produced rather than on ensuring probe coverage. Additional information an automated ultrasonic systems is given subsequently.

As with all NDE techniques, it is important that a written procedure relevant to the application is available and applied by the technician, who should be competent in the technique and preferably be experienced on similar applications or previously qualified on representative test pieces.

Ultrasonic inspection is a valid technique for most materials over a wide variety of component diameters and wall thickness ranges (see Ref 17), although it is most commonly used for in-service wall thickness monitoring of carbon steel and low-alloy steel pipe work, tanks, and pressure vessels. There is effectively no upper limit on pipe diameter and very thick sections can be effectively inspected. However, there is an effective practical lower limit as on small diameter pipe work. (Rocking of the ultrasonic probe can cause unacceptable variation in read-

ings). Small diameter "mini" or "button" probes can be used to partly alleviate this problem, but it is still problematic to get reliable ultrasonic wall thickness readings on pipe work below a certain diameter, typically around 50 mm (2 in.) in diameter. It is advisable to back up such readings with other techniques such as radiography, particularly at welds.

There is also an effective lower limit on wall thickness that can be accurately recorded by ultrasonic techniques. Below 3 mm (0.12 in.) wall thickness, an ultrasonic reading is, at best, indicative and certainly below 2 mm (0.08 in.) is best backed up by radiography. Depending on the wall thickness, application, procedure used, and skill of the operator, uncertainty in the readings obtained is often quoted as being a variation of approximately 0.5 mm (0.02 in.), but this can be greater if conditions of access and surface preparation are less than optimal. Such potential variation should be accounted for in any subsequent use of this data in a fitness-for-purpose review.

To maximize the prospects for obtaining reliable results from ultrasonic inspection, the following conditions should be addressed:

- The object of the inspection should be clearly defined, i.e., whether it is to detect and size general wall thinning, discrete pitting, or other defined defect.
- The procedure should be written specifically to ensure that the defects defined above can be realistically detected and sized for the particular component under inspection.
- Where there is uncertainty regarding the nature of likely defects, the procedure should ensure that the scope is maximized to cover as many options as possible regarding, for example, beam angle so that probability of detection is optimized.
- Any geometric peculiarities of the component to be inspected should be borne in mind in developing the procedure and may require specific testing of technicians in the use of the technique on such geometries.
- Where external coatings are left in place, the procedure should require these coatings to be checked for bonding and attenuation prior to the inspection commencing.
- Access should be optimized to ensure full coverage of the component to be inspected. The procedure should require the technician to report any areas that were not accessible for inspection because these may subsequently need to be inspected by other means.
- The technician carrying out the inspection should be qualified and experienced in the relevant technique, ideally confirmed by test on realistic test pieces.
- Inspections should be suitably qualified as appropriate and the results subsequently reviewed, including sample cross checking where necessary for critical applications.

Where a generic procedure for the technique is used, this procedure should be reviewed and

amended as necessary to take account of any particular geometric or access factors specific to the component to be inspected.

Automated Ultrasonic Systems. To further enhance ultrasonic inspection, automated ultrasonic systems have been developed. The most widely used ultrasonic technique is the pulse-echo technique. In order to enhance the reliability of this technique, specialized automated systems can be deployed. These systems facilitate single/multiple probe inspection and provide images of the component via sophisticated data collection, processing, and analysis software.

In reliability terms, the main advantage of these systems, over the use of manual inspection, is that they remove the operator from the "front-end" of the inspection, thereby ensuring full inspection coverage via preprogrammed manipulation and couplant monitoring. Another main advantage over manual inspection is the ability of automated systems to monitor component degradation via comparison of stored data/component images. Automated pulse-echo is ideally suited to:

- Weld inspection (using multiple probes)
- Corrosion mapping/monitoring (using a single probe or multiple probes)

Phased array is an ultrasonic pulse-echo technique with which it is possible to quickly vary the angle of the ultrasonic beam using focal laws to scan a component, which may be achieved by probe manipulation or without moving the probe itself, allowing multiangle inspection from a single probe position. When applied to the inspection of welds, for example, a number of advantages are afforded:

- Reduction in the number of probes/scans required (reduced inspection time)
- Increased coverage for restricted access areas
- Optimized inspection (using, e.g., different wave modes and beam focusing)
- Potentially easier interpretation of images of the component inspected

Ultrasonic continuous monitoring using flexible mats consisting of multielement arrays of ultrasonic transducers can allow the continuous monitoring of the wall thickness of vessels and piping. These flexible devices, typically 50 mm (2 in.) wide by 500 mm (20 in.) long, are permanently bonded at specific locations to vessels and piping, potentially providing an assessment of the corrosion or erosion rate via a computer-based monitoring package. Alternatively, a conventional ultrasonic flaw detector may be used with a data logger and switching device (multiplexer) for connecting the various transducer elements in turn. These devices are useful where inspection by conventional means (e.g., manual ultrasonics) is difficult or impossible due to component geometry, location, presence of insulation, or hazardous inspection conditions or on unmanned installations allowing remote interrogation.

Long-Range Ultrasonics. Recent developments have been made in the application of long-range ultrasonic techniques, which are particularly useful in the inspection of long lengths of insulated pipe work or pipe work that is largely inaccessible (e.g., pipelines that go under road crossings or for inspection under vessel saddle supports or of subsea risers). This technique has the advantage that only a small area of insulation/cladding needs to be removed to give access to the pipe surface rather than the whole length of pipe having to be exposed for conventional ultrasonic inspection.

In long-range ultrasonics, various wave propagation methods are applied. In one system, a particular type of sound wave, Lamb waves, are generated in the pipe wall, which acts as a cylindrical wave guide allowing inspection to be carried out over a range of several tens of meters from one site. Defects cause the waves to be reflected back to the detector, but interpretation can be complicated, particularly in complex pipe runs and the technique is generally confined to monitoring sections of relatively straight pipe runs with few offtakes, although recent developments have allowed the waves to be "steered" so that more complex geometries can be tackled. The technique indicates the location and approximate size of defects that can then be more accurately sized by application of conventional or specifically designed ultrasonics at the identified defect location.

There are several proprietary systems available for carrying out long-range ultrasonic inspection. All of these systems require operators with specific training, experience, and qualifications (in addition to basic ultrasonic qualifications), particularly for the process of data interpretation.

In a typical application for inspection of long lengths of pipe, low-frequency, guided, ultrasonic waves are used to carry out a 100% volumetric inspection. A single point of access to the pipe surface is all that is required to attach the encircling transducer unit. Liquid couplants are not required; the transducer unit relies on clamping pressure. Ultrasound can be transmitted in one or both directions along the pipe, and the wave format is changed by sudden changes in wall thickness due to the presence of flaws. These techniques are most sensitive to an overall reduction in the pipe cross-sectional area, i.e., the detection of general corrosion rather than discrete pitting or isolated cracks.

Guided wave techniques are particularly applicable to the detection of corrosion on internal or external pipe surfaces in situations where access is restricted. A system limitation is that the maximum operating range varies according to pipe diameter, geometry, contents, coatings/insulation, and general condition. In particular, the presence of sound-absorbing coatings or material in contact with the pipe can greatly reduce the operating range.

Internal rotary inspection system (IRIS) is an ultrasonic technique for the NDE of boiler and heat exchanger tubes consisting of a

high-frequency ultrasonic immersion probe inside a rotating test head. The system provides coverage of the full circumference and full wall thickness as the probe is scanned axially along the tube. A high standard of cleaning to allow transmission of the ultrasound is required prior to deploying this technique so coverage can be limited on tubes that are difficult to clean properly in situ. It can give useful semi-quantitative data on residual wall thickness, but the need for thorough cleaning tends to restrict its use.

The electronic magnetic transducer (EMAT) system is a development that can be used on boiler and heat exchanger tubes but, unlike IRIS, the EMAT technique specifically requires the presence of a heat-induced oxide layer in order to operate. This scale buildup is normal on boiler-style tubing and the technique eliminates the requirement for cleaning prior to inspection. However, because this oxide layer is required, inspection coverage can be limited where this oxide layer is incomplete.

Time-of-flight diffraction (TOFD) is a further development of the conventional ultrasonic technique. Time-of-flight diffraction is a very sensitive two-probe (sometimes single-probe) technique that works by accurately measuring the arrival time of ultrasound diffracted from the upper and lower extremities of a flaw, most commonly used on welds. Sizing can be accurate as the time difference between the signals obtained from the top and bottom edges is used to assess the size. Generally, TOFD requires two ultrasonic probes acting as transmitter and receiver to be scanned as a pair on either side of a weld. An electronic digital record or hard copy image is produced, but specialist training is required to ensure that technicians have the required competence in applying the technique and in interpreting the results produced.

With TOFD, best results are achieved with skilled operators and specialist equipment and software capable of generating high-resolution images of the component. A number of systems are commercially available. Scanning of the component can be performed in a variety of ways, from manual scanning with encoded positional feedback for simple site applications, to fully automated inspection processes.

Time-of-flight diffraction is ideally suited to:

- Rapid screening of simple weld geometries (probes placed on either side of weld)
- "Fingerprinting" of critical components
- Critical assessment and sizing of flaws
- Monitoring of flaw growth

When used for weld screening, TOFD may not detect unfavorably orientated flaws such as transverse cracks, depending on the orientation of the probes and the level of interpretation. In addition, due to the very high inspection sensitivity utilized with TOFD inspection, small flaws that are not serious can sometimes mimic more serious flaws such as cracks; because of this, characterizations based on TOFD alone should be treated with caution. When accurate flaw

characterization is needed, additional scanning using other scan patterns and the pulse-echo technique will often be necessary. The principle of TOFD is outlined in Fig. 2 (Ref 26).

Radiographic Inspection

Conventional Radiographic Inspection.

Radiographic inspection is the detection of material loss by the variation in applied radiation (gamma or x-ray), passing through a component and impinging on a film or other radiation detection medium. X-ray equipment ranges from about 20 kV to 20 MV (the higher the voltage, the greater the penetrating power of the radiation and the greater the thickness of component that can be tested). Gamma radiography is carried out using radioactive isotope sources

(e.g., cobalt-60, iridium-192, and selenium), although, due to the hard radiation characteristics, its sensitivity is generally less than that achievable by x-ray radiography. It is widely used for fieldwork because of its greater portability.

Because it is sensitive to material loss, radiography is better suited to the detection of volumetric defects such as slag or porosity. Detection of planar defects or cracks will depend on length to depth ratio, the gape or opening of these defects, and the misorientation of the radiation beam from the axis of the defect. This feature needs to be borne in mind, particularly with regard to crack detection. It is often necessary to perform radiography from two or three different positions and orientations to ensure a realistic prospect of detecting cracks in a variety of planes.

Traditionally, radiography has produced a film as hard copy of the inspection results, although more recent techniques do not expose a film but instead record results electronically as a digital image that can be subsequently printed or stored electronically.

Considerable interpretation is required of the resultant film or digital image in order to classify and size any defects. Such interpretation needs to be undertaken by a suitably qualified and experienced radiographic interpreter. Defects are identified by changes in the density of the developed film. The film density is related to the exposure it has received from the radiation. The gradient of the film characteristic curve of density against exposure determines how visible small changes in exposure (i.e., small changes in wall thickness) are. This characteristic of the film is its contrast. This tends to increase with film density, thus high densities are beneficial in the detection of defects, although there are practical limits on the level to which density can be increased because of the reduction in transmitted light intensity.

Image quality indicators (IQIs), commonly comprising straight wires of differing diameters, are placed on the object under test and imaged when the radiograph is taken. The smallest wire diameter that is visible on the radiograph then gives a guide to the sensitivity achieved.

There are important health and safety issues to be dealt with by any company planning to undertake radiographic inspection. Regulations exist that cover the storage and use of radiation sources, shielding and collimation, job planning, contingency for emergency response, training and competence of personnel, work planning, systems of work, and so forth. Procedures covering the full range of the activity from planning, through execution to interpretation and reporting should be developed and followed at every stage.

Recent Developments in Radiography

Recently, a number of systems have been developed that use smaller, highly collimated sources in a controlled manner. This allows radiography to be carried out within a much-reduced controlled area. Typically, the controlled area can be restricted to only 3 m (9.9 ft), compared with tens of meters for conventional radiography. This has the advantage that normal plant work can continue relatively undisturbed during radiography work. In addition, dose rates to classified radiation workers are reduced.

Flash/profile radiography is a useful technique for the detection of external corrosion on pipes under insulation or for the detection of wet insulation that could become a site for corrosion. The technique uses a short radiation exposure time, and the beam is arranged tangentially to the pipe wall so that corrosion of the external wall shows up as a variation in the profile of the pipe.

It is normally applied to pipes up to 300 mm (12 in.) outside diameter but can be applied to items with diameters up to 1 m (3.3 ft) given

Fig. 2 The two probe basis for the time-of-flight diffraction technique. The locations of the crack tips are determined from the time differences between the lateral wave and the pulses that follow paths $p_1 + p_2$ or $p_3 + p_4$. These paths correspond to t_1 and t_2 , respectively, in the lower figure. Source: Ref 26

sufficient source to film distance and radiation output. The technique uses x-ray or gamma-ray equipment with a low radiation exposure time, fast reacting x-ray films in conjunction with intensifying screens, or digital detection media. It saves costs normally attributed to the removal and reinstatement of insulation and associated scaffolding. Contrast and resolution of the image are not as good as that for conventional radiography because of orientation of the radiation beam relative to the component, the limited radiation available, the large grain film, and the relatively large focal spot of the sources.

Recent developments have complemented flash radiography. These involve hand-held radiographic systems using a source such as gadolinium-153 in combination with a solid-state scintillator, which converts the transmitted radiation into electrons. The quality and output of the source determines the maximum length of the beam path in the lagging when looking for CUI. Special gadolinium-153 equipment can allow measurement of pipe wall thickness when passing the radiation through the center of the pipe.

Real-Time Radiography. There have been some recent developments regarding real-time radiographic imaging. One proprietary system is a development of flash radiography and utilizes a hand-held image intensifier coupled to a low-energy gadolinium radiation source. The method of inspection is to move the hand-held unit around the pipe circumference such that 100% coverage of the pipe external surface is obtained. The radiosopic image is viewed on a monitor or helmet-mounted real-time display. It is applicable to piping with thermal insulation to detect the presence of CUI. The radiation is projected through the thermal insulation, at a tangent to the pipe wall, to the image intensifier such that corrosion damage can be observed in profile on the real-time display.

In another development of real-time radiographic imaging, a profiler has been developed that allows wall thickness to be determined. The system consists of an isotope or x-ray source, a transmission radiation source, a microchannel-plate (MCP) x-ray detector, a laptop or palmtop computer, and proprietary software (Fig. 3). The software converts the radiation-intensity output into linear-equivalent thickness data, which are presented on the computer monitor. The output of a collimated gadolinium-153 isotope source is

directed to a special scintillator. The scintillator electronics contain the equivalent of a low-level x-ray camera. In turn, the scintillator is coupled to a photomultiplier tube whose electronics are matched to the scintillator output (Ref 27). The profiler can be used as a rapid screening tool to inspect long lengths of insulated pipe and can identify areas of potential concern that can then be targeted for selective insulation removal and closer inspection by another technique such as ultrasonics.

Other Commonly Used Inspection Techniques

Dye penetrant inspection is one of a range of techniques suited only for detection of surface-breaking (rather than subsurface or embedded) defects and is generally used on nonmagnetic materials. This technique requires thorough cleaning and decontamination of the surface to be inspected prior to application of the dye. The dye is left on the surface for a set period to allow the dye to be drawn into any surface-breaking defects by capillary action. The excess dye is then removed from the surface and a developer is applied. The developer draws any dye back out of the defects and shows as a stain against the neutral-colored developer.

Dye penetrant is a low-cost technique that can be used to cover a large area of inspection fairly quickly. The technique is straightforward and practitioners can be readily trained in its use and interpretation. Dye penetrant is good at detecting pits and cracks but may not detect very fine cracking unless the dye is left for a considerable period. Detection is also highly dependent on obtaining a good surface finish because dye can be trapped in surface laps and discontinuities that could be confused with cracks, particularly in confined or restricted geometries. Conversely, excessive force in surface preparation, such as heavy grinding, can result in surface-breaking cracks being smeared over and failing to absorb dye. Fluorescent dyes and ultraviolet lighting can be used to increase the contrast of indications, making them more visible to the operator and hence increasing the sensitivity of the technique.

Magnetic particle inspection is another of the techniques for surface-breaking defects, but it is used on magnetic materials. It is based on the

fact that defects on the inspection surface interrupt lines of induced magnetic flux.

This technique is more tolerant of surface finish than the dye penetrant technique, but some surface preparation is still required. Additionally, the component may need to be demagnetized if there is any residual magnetic field within the component. A thin coating of contrast paint may be applied to the component to aid subsequent viewing of defects. The component is then magnetized, either by the application of a permanent magnet or electromagnetic yoke, while magnetic particles either in dry powder or liquid suspension are applied to the surface. If the component is sound, the magnetic flux is predominantly contained within the material; if, however, there is a surface-breaking flaw, the magnetic field is distorted, causing local flux leakage around the flaw. The magnetic particles align themselves with this magnetic flux leakage and any defects can be detected. The particles accumulate at the regions of flux leakage, revealing the flaw as a line of iron particles on the component surface. Fluorescent magnetic inks may be used to increase the contrast of indications, making them more visible to the operator and hence increasing the sensitivity of the technique.

For optimum detection, it is important to have some knowledge of the likely orientation of cracks to ensure that the magnetic field is applied as near to perpendicular to the defects as possible. It is therefore necessary to inform the technicians carrying out the inspection of the types, orientations, and sizes of the flaws being sought along with information on geometric or other features of the component that may produce confusing indications.

Eddy-current inspection is another technique used mainly for detection of surface-breaking defects. When an alternating current is passed through a coil close to a component surface, eddy currents are induced in the component close to the surface and these in turn affect the current in the coil by mutual induction. Surface-breaking flaws and material variations in the component affect the strength of the eddy currents. Therefore, by measuring the resultant electrical changes in the exciting coil, flaws can be detected.

The skin depth, which is a function of the permeability of the material and the frequency, determines the depth of penetration of the eddy currents. In ferromagnetic material the skin depth is very small, and the technique will detect only surface-breaking defects. In nonmagnetic material it provides some subsurface capability and can give some indication of the depth of a defect.

No surface preparation is necessary and protective coatings can be left untouched. It is therefore becoming increasingly popular in applications where magnetic particle inspection would normally be used but where the removal and subsequent need to reinstate protective coatings is problematical, for example, around the splash zone of offshore oil and gas risers.

Fig. 3 Components of a real-time radiographic imaging profiler system for measuring pipe wall thicknesses. The monitor displays the signal pulse readout. Source: Ref 27

However, specialist training is required to allow the technician to interpret the signals and spurious indications that can result from local variations in material permeability, particularly at welds.

Acoustic emission inspection is a specialized technique that can be applied to some extent in the detection of corrosion, although its main use is currently in the detection and monitoring of cracks and in leak detection. An array of sensors is strategically placed on the component or structure to be inspected. The sensors "listen" for acoustic emissions, and from this array the relative time of an acoustic event is measured at each sensor from which the location of the cracking or corrosion activity can be determined (Ref 28). Acoustic emission can be used to determine only active features, e.g., cracks that are still propagating rather than any that have been arrested (Fig. 4). It is a highly specialized technique requiring customized equipment for monitoring and also sophisticated computer software for interpretation. When used in an operating plant, the signals from active sites can be difficult to differentiate from background noise, thus great care and skill are required in the use of this potentially powerful technique.

Magnetic flux leakage (MFL) is a technique based on the magnetization of the component being inspected using a strong magnet located inside the test probe. It is therefore applicable only to ferromagnetic materials. As the probe encounters a wall thickness reduction or a sharp discontinuity, the flux distribution varies around that area and is detected either with a Hall-effect transducer or an inductive pickup coil. The amplitude of the signal obtained from any wall loss is proportional to the volume of material that is missing from the region examined. This means that the amplitude does not necessarily correspond to the decrease in thickness of the wall. The technique is not able to discriminate between material loss on the near surface and material loss on the far surface. Magnetic flux leakage is used as a qualitative technique and is unable to give an accurate assessment of the remaining wall but can be useful in identifying locations of corrosion that need to be examined further using other techniques. Unlike magnetic particle inspection, the method is not limited to surface-breaking or near-surface flaws.

Magnetic flux leakage found wide use in the NDE of tank floors because it is quick to apply and can detect material loss on both surfaces of the floor. The requirement for the sensor to be

placed between the poles of a magnet means that the technique is unable to give 100% coverage of a floor up to vertical obstructions and side walls. The wall thickness that can be inspected by MFL is limited by the requirement to achieve magnetic saturation.

Pulsed eddy-current inspection is a technique for detecting corrosion and erosion and measuring average-remaining wall thickness in a given sampled area. It is a volumetric technique, therefore, unlike ultrasonic thickness measurement, it measures the amount of material over an area (footprint) rather than the wall thickness at a precise point. It can therefore determine average loss over the footprint area but cannot differentiate between uniform loss and pitting corrosion and may miss fine pitting completely.

A transmitter coil produces a magnetic pulse that induces eddy currents within the component wall. The eddy currents in turn produce a second magnetic pulse, which is detected by the receiving coil. The system monitors the rate of decay of the eddy-current pulse within the steel wall. The average thickness is derived from the comparison of the transient time of certain signal features with signals from known calibration test pieces.

This technique is quick to apply and can test through nonconductive and nonmagnetic material such as insulation, passive fire protection, and concrete layers up to 100 mm (4 in.) thick. It can be confused by adjacent metallic components, thus a skilled and competent technician is required to assess the requirements before this technique is applied. It is suitable only for low-alloy steels and is unable to differentiate defects on the top and bottom surfaces. It can be useful, however, as a quick scanning tool to highlight areas that require further investigation by more sensitive techniques.

Thermography uses an infrared camera or monitor to observe and record the skin temperature, or the variation over an area, of the surface of a plant item. Depending on the imager, variations in surface temperature as small as 0.1 °C (0.2 °F) can be detected.

Inspection by thermography can detect faults in any component where the faults result in a change in surface temperature. Variations in heat transfer through the wall may be attributable to wall thinning, the buildup of scale, or component blockage. It may indicate the presence of wet insulation and the potential conditions for CUI.

The size of defect that can be detected will depend on the optical parameters of the system

and the resolution of the camera. In assessing the results, the emissivity of any paints or coatings on the component need to be considered. Reflections of sunlight can also distort readings, so it is best to carry out thermography on an overcast day. Where thermography is used to monitor temperature over a period of weeks or months, care should be taken to ensure that the camera parameters are the same and that the observing conditions are constant.

The technique is noncontacting and only line-of-sight to the surface under examination is required. It is quick and easy to apply but can detect only defects and/or faults that cause a change in heat flow or the surface temperature of the item. It measures only surface temperature, and there should be no misunderstanding that it can in some way "see" defects through the metal wall.

Neutron backscatter is a screening technique that can be used for the inspection of insulated pipe work and vessels to locate areas of wet insulation, which are potential CUI sites. Neutron backscatter devices (hydrodetectors) work by emitting fast (high-energy) neutrons into the insulation from a neutron source. These neutrons are slowed down after collision with hydrogen nuclei in the areas of wet insulation. A detector, sensitive to slow (low-energy) neutrons, then counts the slow neutrons that are backscattered. Low counts per time period mean low moisture while high counts per time period mean high moisture, i.e., an area of wet insulation.

Devices typically consist of a neutron source and detector assembly on the end of a telescopic pole. This allows access to hard-to-reach areas of pipe work and vessels and coverage of large areas or lengths of pipe work can be achieved.

There are distinct limitations of this technique. Given the nature of the neutron source (which by their nature are very penetrative), the backscatter thus created may be resultant from either wet insulation or from the internal process environment if it contains water. The technique therefore cannot be relied on if the primary process environment of the equipment being inspected contains even modest quantities of water.

Corrosion of Structures

John E. Slater, Invetech Inc.

THE PREVENTION of metallic corrosion in structures, particularly the consideration of its effects in initial design and fabrication or later during in-service inspection and retrofit, is vital in ensuring the expected longevity of the structure. Indeed, in many cases, structures may have to last well beyond their originally anticipated lifetimes. For example, the lives of structures in Europe that contain metal extend in some cases back many hundreds of years.

When considering the ramifications of corrosion and its prevention in different types of structures, it is useful to group such structures into various categories. Thus, the modern high rise—whether an office building, an apartment building, a condominium, or a special-purpose building such as a hospital—poses particular problems related to the corrosion of major structural components (which may be either totally metallic or may contain metallic material). This creates the necessity for corrosion considerations in any connector assembly used to tie the curtain-wall system on the building back to the structural frame or to the backup wall system. In low-rise structures, similar concerns exist, but may be less critical when the structure is only a few stories high.

Under such circumstances, the possibility of danger to people and property resulting from failure of, for example, curtain-wall tie systems may be less. Nevertheless, failure of metallic materials within the structure may lead to unsightliness or to possible lack of weathertight behavior. Both may require extensive reworking of the structure to reestablish adequate building performance.

Parking structures are frequently of conventionally reinforced concrete or prestressed/posttensioned construction. Where such structures are in the snow-belt areas of the country or where chlorides may intrude because of the proximity of marine environments, the reinforcement may be at risk from corrosion. Stadiums are another example in which either steel-frame or concrete-frame designs are used. In these cases, certain approaches may be needed to ensure structural integrity, particularly in view of the safety of the many thousands of people who visit the structure and fill it to capacity.

Bridges have received much attention with regard to corrosion. This has been particularly prevalent in the snow-belt states, where deicing

salt application has led to significant premature deterioration of decks and supporting structures. Supporting structures also suffer damage because of saline water intrusion, particularly in the splash zone of reinforced concrete structures. The use of weathering steels can be a problem in bridges, especially where design or construction practices do not adequately account for the particular limitations of this type of steel.

Other specialized structures in which corrosion conditions may be a concern include sewage plants, which may have isolated situations related to contaminated water and the use of treatment chemicals. Buildings or structures can be used to house or support chemical plants and/or utility plants. In the latter case, specific aspects of corrosion prevention in nuclear plants, especially containment buildings, have been the subject of critical review. Because many nuclear containment vessels are designed with posttensioned concrete, the longevity of any corrosion-protection system applied to the posttensioning tendons is critical. This article does not address specific interactions with manufactured industrial chemicals, because this area is more reasonably the province of general or specific knowledge related to the particular chemical to which the building material will be exposed.

Metal/Environment Interactions

The most common metallic material used in structures is low- or medium-carbon steel. Specialized or strengthened materials, including heat treated steels, stainless steels, and nonferrous metals, are sometimes employed; use of these materials is the exception rather than the rule (they are discussed when appropriate in this article). The specific interactions that are considered are the reactions of steel with the atmosphere in all of its forms, including polluted atmospheres, interior atmospheres, and internal atmospheres (for example, in a cavity wall). The major criteria determining the performance of unprotected metal include the corrosivity of the atmosphere, the temperature, and the time of wetness of the metal.

Considerable effort has been expended in determining the reaction of steel with cementi-

tious materials, which include mortar, concrete, and their variants. The chemical that typically controls corrosion behavior under these circumstances is the calcium hydroxide ($\text{Ca}(\text{OH})_2$) introduced into the cementitious material by the portland cement or, in the case of mortars, lime. The reaction of $\text{Ca}(\text{OH})_2$ with atmospheric carbon dioxide (CO_2) is an important degradation mechanism that radically changes the behavior of steel in contact with or embedded in the cementitious material. The other major factor that influences the corrosion of steel is the introduction of chloride ion (Cl^-) into the cementitious material. Chloride may play a decisive role in causing the cementitious material to change from a protective to a nonprotective environment with regard to embedded steel.

This article discusses the generic situation of steel reacting with the environments found in structures. Two environments are specifically discussed: atmospheric and cementitious environments. The utility of different corrosion-protection methods is described. Examples of problems that have arisen in the corrosion performance of steel are described.

General Considerations in the Corrosion of Structures

Corrosion of Steel in the Atmosphere.

Steel corrosion in the atmosphere is typically a function of temperature, humidity, and the presence in the atmosphere of components that increase the corrosivity of the environment (see, for example, the article "Atmospheric Corrosion," *ASM Handbook*, Volume 13A, 2003). The temperature/humidity ratio is particularly important, because the interaction among these factors leads to a function known as the time of wetness, during which a film of liquid is present on the surface of the steel. Corrosion occurs by an aqueous corrosion mechanism during the time the film is present on the steel surface. The thinner the film, the easier is the diffusion of oxygen through the film to drive the corrosion reaction.

The presence of agents in the atmosphere that can dissolve in the liquid film and promote or inhibit its production by changing the dew point

can markedly influence the corrosion behavior of the steel. Pollutants in the atmosphere, particularly sulfur dioxide (SO₂) and related compounds that can lead to acid rain, influence the corrosion behavior of the steel by acting in several ways, such as:

- An increase in conductivity, and therefore the corrosivity, of the liquid film
- Changes in the relative humidity at which the film forms
- Alterations in the corrosion product films that may form on the steel

Therefore, the corrosion behavior of steel used in structures can be expected to be a function of the geographical location, which in turn will determine the temperature, humidity, and degree of pollution that exists. This behavior is indicated in Table 1.

Corrosion in marine environments is a specialized subset of atmospheric corrosion because of the influence of wind-blown or particulate sea salt that may contact exposed steel. Sea salt is particularly aggressive to steel, possibly because of the concentration of magnesium chloride (MgCl₂) it contains. Sodium chloride (NaCl), the major constituent of sea salt, is deleterious to the corrosion behavior of steel because of its effect on the conductivity of the liquid film and its destruction of protective corrosion product. On the other hand, MgCl₂ acts to acidify the liquid film and, by its deliquescent action, to increase

the time of wetness. The corrosion rates of structures in marine environments are considerably higher than in any other type of environment. The dramatic increase in the corrosion rates of steel in marine locations is indicated in Table 1. Additional information can also be found in the articles "Corrosion in Seawater" and "Corrosion in Marine Atmospheres" in this Volume.

Specialized environments exist in which pollutants are present as a function of the particular use or location of the structure. Chemical plant and refinery buildings and structures may be vulnerable to atmospheric pollutants produced within the plant and may require protective measures. This type of damage is beyond the scope of the present article, and the reaction of steel to such environments is best determined by noting the effect of the pollutant on the corrosion of steel (Ref 2).

The atmosphere within closed structures will usually be different from that for external surfaces. In general, the presence of pollutants may be significantly reduced, and the control of temperature and humidity may mean the overall environmental corrosivity is significantly lower than that for outside surfaces. However, there can be circumstances that alter these effects. For example, the well-known barrier effect of internal walls, which is related to their containment of the internal environment, may be breached at certain locations. The result may be that air escapes from the interior of the building into the

cavity. If structural or other steel is present in this cavity, the interaction of the steel with air, which may be deliberately humidified, can lead to condensation and subsequent corrosion problems that would otherwise be unanticipated.

Such problems have been noted in the past, both for the structural steel framing and also for elements in the system that tie the external cladding back to the frame of the building. Therefore, concern is necessary not only for the influence of the external environment on the corrosion of steel, but also for the effects of the internal environment.

Fireproofing is often mandated by fire codes for structural steelwork within buildings. In the past, fireproofing was used that contained corrosive constituents. Under circumstances in which moisture levels at the structural steel may increase (because of exfiltration of humid air or infiltration of moisture), the corrosive constituents in the fireproofing can lead to unacceptable corrosion of the steel. This problem is addressed in ASTM E 937, which is a standardized test for determining the corrosivity of fireproofing materials under standardized conditions (Ref 3). The use of coatings that meet conditions related to this test is required by many codes and should be mandated by the architect or engineer.

Whenever steel is used in buildings, there is always the possibility for galvanic corrosion to occur. Galvanized conduit may contact bare steel. Copper-base alloys are used as wiring, for example, in lightning conduction rods. In general, the relative positions of metals in the galvanic series for seawater will normally dictate whether or not there is a potentially significant problem for galvanic corrosion from structural elements in contact. The environment surrounding the galvanic couple will have a significant effect; more severely corrosive environments allow more galvanic activity to occur. Therefore, the impact of galvanic corrosion must be an ever-present concern.

The use of lower-strength steels generally indicates that environmental/mechanical interactions leading to unexpected brittle failure are unlikely to occur in normal structural environments. The use of higher-strength steels (particularly those of the quenched-and-tempered variety) may increase the likelihood of stress-corrosion or hydrogen embrittlement failures, especially in more aggressive environments such as marine conditions. Compounding the problem is the welding that may be performed, for example, on bridge structures. Therefore, quenched-and-tempered steels of the ASTM A 709, grade 100, type, which have yield strengths in the 690 MPa (100 ksi) range, must be welded carefully so as not to create hard regions in heat-affected zones that are susceptible to hydrogen embrittlement.

Similar considerations pertain to the area of embedded posttensioning steels. These steels are typically of the cold-drawn type (not quenched and tempered), corresponding to such standards as A 416, grade 1860 (1860 MPa, or 270 ksi,

minimum ultimate tensile strength for seven-wire strand), and A 421 (1655 MPa, or 240 ksi, minimum ultimate tensile strength for 6.4 mm, or 1/4 in., diam, uncoated wire). Although laboratory test data indicate that cold-drawn steels are considerably less susceptible to failure by hydrogen embrittlement than their quenched-and-tempered counterparts, care must be taken to minimize the aqueous and/or atmospheric corrosion of such steels before and after concrete placement.

The atmospheric corrosion of other nonferrous metallic materials commonly used in structures is of less concern. Aluminum can be used for a variety of building components, including windows and door frames. If the aluminum is protected from direct contact with uncured mortar or concrete and if anodized coatings are specified, little atmospheric corrosion is noted except under severe marine conditions. Zinc is typically used only as a protective coating for steel and is covered in the section "Protection Methods for Atmospheric Corrosion" in this article.

Steel in Cementitious Materials. The behavior of steel in contact with cementitious materials (concrete and mortar) is generally governed by the properties of the portland cement that is a constituent of the mortar or concrete. Portland cement is an alkaline material; the alkalinity results from the presence of Ca(OH)_2 and other soluble alkali salts. The pH of a saturated Ca(OH)_2 solution is approximately 12.5. Reference to the Pourbaix (potential-pH) diagram for iron (Fig. 1) shows that, under these circumstances and in the presence of moisture and oxygen, the steel will be in a passive condition because of the formation of a thin film of oxide—generally considered to be γFeOOH (see also the article "Potential versus pH (Pourbaix) Diagrams," *ASM Handbook*, Volume 13A).

The effect of pH on the corrosion rate of steel in aerated water is shown in Fig. 2. If the oxygen is depleted or if the cementitious material is allowed to dry significantly, then the passive film may well be disrupted. However, the corrosion rate is still expected to be low because of the high resistivity of the concrete and low driving force

for the corrosion reaction. However, there are pollutants in the cementitious environment that can modify this behavior, leading to significant corrosion of steel.

Concrete is a hard, dense material that consists of cement paste surrounding aggregate particles. The major difference between mortar and concrete is in the size of the aggregate. Concrete contains a high proportion of large aggregate, such as gravel and crushed rock. Steel that is embedded in concrete, generally as reinforcement, can be of two main types. In conventional reinforced concrete, reinforcing bars are used to support the tensile loading, because of the relative weakness of unreinforced concrete in tension versus its significant strength in compression. Reinforcement is sized and placed according to requirements determined by the structural engineer.

Other types of reinforcement in concrete are deliberately stressed in tension to place the concrete into residual compression. For prestressed concrete, this is typically accomplished by placing the stressed steel into the concrete form and pouring the concrete around the steel. Once the concrete has cured, then the external tension on the steel is released. The bond between the steel and the concrete now places the surrounding concrete into compression, leading to the well-known concept of prefabricated, prestressed concrete.

This same effect can be achieved by post-tensioning, in which the unstressed steel is placed in the concrete form before the concrete is poured. The steel is typically prevented from developing a bond with the concrete during the pouring process. After pouring and curing of the concrete, the steel embedded in (but separated from) the concrete is tensioned and the tensioned steel is anchored to the ends of the concrete structure. In this way, the concrete around the steel is placed into tension.

Other steel components that may be embedded in concrete include water lines (which are typically galvanized steel) and the forms used as containment during the concrete pouring process. In many cases, the forms are removed; in others, the forms remain in place. As such, the forms are exposed to the atmosphere on their outer surface and to the concrete environment on their inner

Fig. 2 Effect of pH on the corrosion rate of iron in aerated soft water at room temperature

surface. Problems can occur during the use of such forms, particularly where additives to the concrete have caused a corrosive situation to occur.

Unanticipated contact may occur between steel embedded in concrete and other metals used in construction. Aluminum can be embedded in or located on concrete, for example, balustrades and lamp posts. If contact can occur between embedded steel and aluminum in corrosive environments, accelerated corrosion of the aluminum can occur, with corresponding galvanic protection of the steel. Although it is conceivable that copper water pipes could contact embedded steel reinforcement, there are no instances of such problems occurring.

The use of mortar is a necessary factor in the construction of brick masonry, and steel is used in such masonry in a variety of applications. The use of steel joint reinforcement to enhance the strength of the masonry by placing a mesh or ladder-type system within the bed joint is a common occurrence. Such a system can also be used to connect two wythes of masonry. Steel ties or anchors are used to anchor masonry curtain-wall systems back to the building frame or to a supporting structure. Typical reinforcements, ties, and anchors are shown in Fig. 3. Although bare steel would suffice in uncontaminated high-pH mortar, it is common practice to use a more corrosion-resistant material. Typically, galvanized steel is recommended and used, either hot-dip or electroplated.

Other metallic components that may contact mortar include window frames and doorways. These may be steel or aluminum. Such steel components can be protected against atmo-

spheric corrosion with organic coatings, but in other cases metallic coatings such as galvanizing can be used. Aluminum components can corrode in the uncured or green mortar environment. In the absence of further corrosion enhancers, the corrosion rate normally drops to a very low level once curing has occurred and the mortar dries.

The corrosion behavior of steel in concrete and mortar as a function of pH can be drastically altered by two factors. The first is carbonation or the reaction of the $\text{Ca}(\text{OH})_2$ with CO_2 from the air. This reaction to form calcium carbonate (CaCO_3) lowers the pH of the cementitious material; the steel may no longer be passive, but can become active and corrode significantly. Carbonation is a function of the porosity of the concrete or mortar, which is a function of such factors as the water/cement ratio, placement adequacy, and vibration/consolidation. In general, mortar is much more permeable than concrete and carbonates much more rapidly. Under these circumstances, the mortar in masonry structures must be considered to undergo carbonation at a relatively early point in its life. To prevent the corrosion of embedded steel due to carbonation, it is common practice to use protective coatings on steels (galvanizing is common) or to use inherently corrosion-resistant materials, such as stainless steels.

The second major contributor to the corrosion of embedded steel in cementitious material is the influence of chloride. Chloride in sufficient quantities prevents the formation of the initial protective oxide film on steel (if the chloride is present in the material mix during the curing process) or, if added later, breaks down the

passive film and allows corrosion to proceed. Possible chloride sources in the mixing process are the aggregate, chloride introduced with the mixing water (a problem frequently encountered in the Middle East, where brackish water is often the only water available), and chloride-containing admixtures deliberately added to the mix as a set accelerant or so-called antifreeze (most commonly calcium chloride, CaCl_2). Chloride can also find its way into the cementitious material after placement and curing, because of the application of chloride to the outer surface. Sources are marine environments, deicing salt placed onto concrete bridge decks, parking structures, and hydrochloric acid washing solutions applied to masonry surface.

The quantity of chloride necessary to cause corrosion of bare steel in uncarbonated cementitious systems depends initially on the stage at which the chloride is introduced. For bare steel in initially chloride-free concrete that is subjected to chloride infiltration from the external surface, corrosion has been found to initiate on the steel when the chloride level reaches between 0.02 and 0.04% by weight of concrete at the concrete/steel interface. When the chloride is present in the mix, the tricalcium aluminate of the concrete can insolubilize a certain portion of the chloride during the curing process. Recognition of this fact initially led to the allowance of additions of 2% CaCl_2 (by weight of cement) to concrete to accelerate set. More recent work, together with the release of bound chloride as concrete ages, has led to a recognition that maximum allowable chlorides in concrete should be a function of both the nature of the steel and the expected service

Fig. 3 Typical metallic anchors (a) to (g) and ties (h) to (o) used in masonry walls

environment of the concrete. The recommendations of American Concrete Institute Committee 201 (Durability of Concrete) are given in Table 2. See the article "Environmental Performance of Concrete," *ASM Handbook*, Volume 13B, 2005.

A compounding factor in the chloride-induced corrosion of reinforcement is the formation of macrocells. Because of the electrically continuous and extensive nature of the typical reinforcement in concrete, differences in chloride concentration and oxygen level at different locations on the steel can occur. Under these conditions, separated anodic (high-chloride, low-oxygen) and cathodic (low-chloride, high-oxygen) areas can easily develop along the reinforcement, particularly where chloride enters the concrete from an exterior surface. This macrocell action frequently leads to severe corrosion at the anodic areas.

Macrocell action can be worsened unintentionally and substantially during concrete repair. The replacement of deteriorated, spalled, chloride-contaminated concrete adjacent to reinforcing steel with fresh, chloride-free concrete can introduce a potent cathode into the system. The result can be accelerated corrosion of the surrounding reinforcement, which can lead to the spall around a spall deterioration phenomenon.

The effect of corrosion on steel-reinforced structures is somewhat dependent on the nature of the steel. The major problem arising from an increased corrosion rate is the production of a voluminous oxide, which occupies a greater volume than the steel from which it was produced. Under these circumstances, significant tensile stresses can be introduced into the surrounding concrete material, leading to cracking and eventually spalling. Calculation of the Pilling-Bedworth volume ratio allows the magnitude of the volume expansion to be assessed, with values typically found between 2 and 4, depending on the exact nature of the corrosion product. The Pilling-Bedworth ratio is discussed in several articles in *ASM Handbook*, Volume 13A, including "Thermodynamics of Gaseous Corrosion," "Kinetics of Gaseous Corrosion Processes," and "Gaseous Corrosion Mechanisms."

The effect on high-strength prestressing steel may not be the same. Such steel typically has an ultimate tensile strength exceeding 1380 MPa (200 ksi) that is produced by cold forming. Steels of this hardness may be susceptible to stress-corrosion cracking or, more probably, hydrogen embrittlement. In this context, corrosion processes that produce hydrogen can be very deleterious to structures containing the post-tensioning or prestressing. This is due to the possibility of hydrogen embrittlement leading to brittle fracture of the steel and loss of compression of the surrounding concrete.

Protection Methods for Atmospheric Corrosion

Various methods are available for protecting steel against corrosion in atmospheric condi-

tions. The protection system is generally a barrier coating or a metal alloying of the steel that effectively introduces a barrier coating by a normal corrosion process. As discussed in this section, design considerations are also critical.

The barrier coatings used to protect steel from atmospheric corrosion are of three main types: organic coatings, inorganic coatings, and metallic coatings. The selection of one of these types of coatings is a function of the expected environmental severity in which the structure is to perform, the corrosivity of that environment, the design life of the structure, and the possibility of further maintenance coating. In other words, coating selection is a combination of both technical and economic considerations.

Design. One of the most important aspects of corrosion protection is consideration of good design practice. Such considerations include:

- Avoidance of upturned angles, channels, and so on, that can collect moisture
- Avoidance of pockets within welded structures
- Grinding welds flush
- Elimination of crevices that can lead to accelerated corrosion

Examples of details to avoid, as well as more corrosion-resistant details, are shown in Fig. 4. Although some of these problems can be mitigated by other corrosion-protection methods, the selection of weathering steels makes adherence to good design and fabrication detailing mandatory (see the discussion of weathering steels later in this section). Refer also to the article "Designing to Minimize Corrosion," *ASM Handbook*, Volume 13A, for additional information on this topic.

Organic coatings are perhaps the most frequently used coatings for protecting steel from atmospheric corrosion. This is true with regard to bulk structural steel. However, components such as fasteners rarely have organic coatings. This is because of difficulties related to the fit of coated fastener systems and the poor durability of such

coatings under abrasion and tightening conditions. It is generally recognized that the quality of the surface preparation is a major factor in the service life of the coating. Perhaps the most extensive evaluation of paint behavior as a function of substrate preparation has been conducted by The Society for Protective Coatings (SSPC), which has issued standards on different degrees of cleaning prior to the application of paints. Uses and applicable SSPC and NACE International standards for various surface preparation techniques are summarized in the article "Paint Systems," *ASM Handbook*, Volume 13A (see, in particular, Table 1 on page 838).

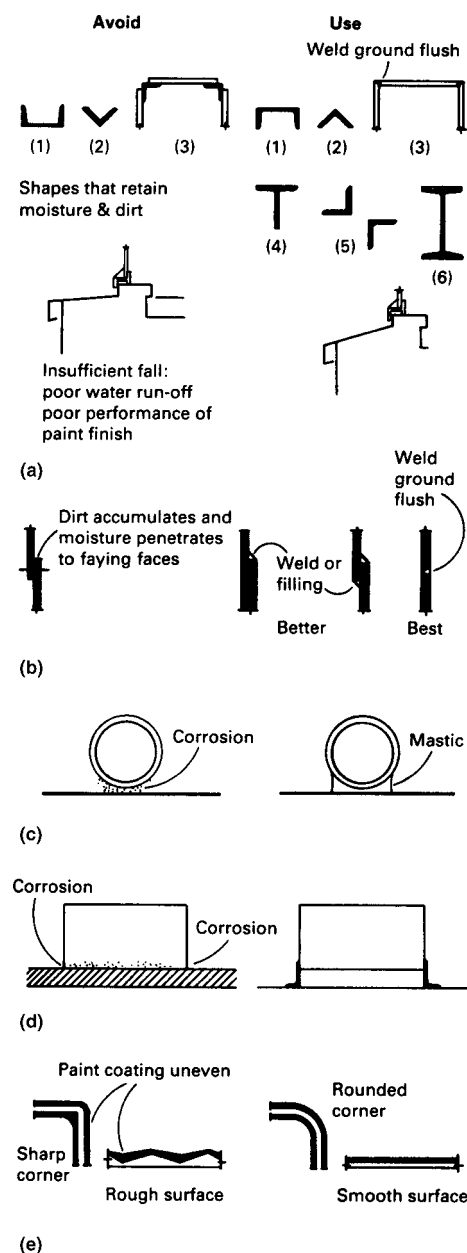

Fig. 4 Design and fabrication details to be considered in corrosion prevention. (a) Constructional members, sills, etc. (b) Joints. (c) Crevices. (d) Air circulation. (e) Corners, edges, and surfaces

Table 2 Recommended maximum water-soluble chloride levels in concrete mix (prior to service) for different reinforced concrete exposures

Type of exposure	Maximum recommended chloride level, wt% of concrete
Prestressed concrete	0.06
Conventionally reinforced concrete in a moist environment and exposed to chloride	0.10
Conventionally reinforced concrete in a moist environment but not exposed to chloride (includes locations where the concrete will be occasionally wetted, such as parking garages, waterfront structures, and areas with potential moisture condensation)	0.15
Aboveground building construction where the concrete will stay dry	No limit

The degree of cleanliness depends on the sensitivity of the paint system to the level of surface cleanliness and on the required longevity of the system. Different methods of surface preparation are available, including centrifugal blast cleaning, abrasive air-blast cleaning, water-blast cleaning, and hand- and power-tool cleaning. Hand-tool and power-tool cleaning are typically employed only where small areas must be cleaned of preexisting scale and paint. It is also important to recognize that contaminants on steel surfaces that are not visible to the naked eye may influence the longevity of the subsequent coating. Inorganic salts on the coating surface may dissolve in water that permeates through the coating, leading to corrosion of the substrate. Standard blast-cleaning techniques typically do not remove such contaminants, but water-blast cleaning does. Again, this becomes a matter of economics and the sensitivity of the coating system to surface contamination.

The selection of a coating system is influenced by consideration of the likely corrosive environment and the consequences of coating failure. Figure 5 shows some typical preparation and coating formulations. The need for increased durability of the coating increases with the corrosivity of the environment. In this regard, much steel is enclosed within building walls, and such steel is frequently only lightly shop primed. Indeed, it has been questioned whether such coating is in fact necessary, based on the environment in which the steel is to perform.

One of the problems in making decisions of this type is that the severity of the environment may not be adequately documented. If there is exfiltration from the building, then condensation on the steel members can occur, resulting in an extended time of wetness and a corrosion rate that is significantly greater than might otherwise be anticipated. Under these circumstances, the thin shop primer may be much less than adequate, and a more rigorous corrosion-prevention system should be considered. Adverse effects on such steel may include the pickup of corrosive constituents (particularly chloride) from other building materials—for example, from mortar during passage of water through masonry walls. If flashing systems are inadequate, then such water may reach structural steel and cause significant corrosion damage. This is another factor that needs to be considered whenever the so-called benign environment within the walls of a building is considered.

Inorganic Coatings. Other forms of coating that are midway between the use of a metallic coating and an organic coating are the inorganic zinc-rich coatings. The life expectancy of this type of material in severe weathering service has not been established, but complete protection of the steel substrate is still provided after 20 years of exposure. Protection in this case is largely the result of the good corrosion resistance of zinc itself. Indeed, it has been pointed out that the cured inorganic zinc-silicate films can be thought

of as a cross between hot-dip galvanizing and a fused ceramic. Because of the absence of organics, inorganic coatings are considered to have the best solvent resistance of any type of protective coating. This makes them very useful for structures in which vapors are present such as chemical plants, petroleum refineries, and production facilities. Further information can be found in the article "Zinc-Rich Coatings," *ASM Handbook*, Volume 13A.

The metallic coating system most commonly used for steel in structures is a zinc coating. These coatings can be applied by hot-dip galvanizing or by electroplating for smaller components, such as bolts. Electroplating lays down a considerably thinner zinc layer than hot-dip galvanizing and the service life is shorter. The service life of galvanized coatings is a function of the coating thickness and the environment in which it will operate. This is illustrated schematically in Fig. 6. Therefore, the thickness of a galvanized coating on structural steel will depend on an assessment of the nature of the environment and the required longevity. In this regard, the severity of the environment within a cavity wall (where zinc coatings are frequently used) is a significant concern. Zinc coatings are described in the articles "Continuous Hot Dip Coatings" and "Batch Process Hot Dip Galvanizing," *ASM Handbook*, Volume 13A. Electroplated zinc products are reviewed in the article "Continuous Electrodeposited Coatings for Steel Strip" in *Surface Engineering*, Volume 5, *ASM Handbook* (1994).

Steel roofing is frequently protected by a 55Al-43.4Zn-1.6Si hot-dipped coating known by the tradename "Galvalume." This coating can be used either as a basis for paint or as a bare protective coating in its own right. The ASTM standard governing composition and thicknesses of this coating is A 792. Compared to a galvanized coating of the same thickness, Galvalume coatings offer a factor of between two and six times greater atmospheric corrosion resistance, depending on the nature of the exposure. The protection Galvalume offers the base steel appears to be a combination of both galvanic and barrier effects.

For small components, other protective systems are available. These include cadmium plating, which is considered to be more corrosion-resistant than zinc in marine environments. Use of cadmium plating is restricted because of the toxicity of the plating solutions and the difficulty of disposal (see the article "Cadmium Elimination in Surface Engineering" in *Surface Engineering*, Volume 5, *ASM Handbook*, 1994). Nevertheless, the general corrosion resistance of cadmium plate makes the process worthy of consideration where allowed.

Weathering Steels. An excellent method of protection against atmospheric corrosion is the use of weathering steels. In this class of materials (typified by ASTM specifications A 588 for buildings and A 709 for bridges), small amounts of alloying elements—typically nickel, chromium, and copper—are added to the steel (Ref 6,

7). Under certain fairly specific situations, these alloying elements are incorporated into the oxide layer that forms on the steel, leading to the formation of a dense, more protective oxide. This oxide serves as a barrier to further penetration of moisture and effectively acts almost as a "self-painted" coating, lessening the need for other coating protection. An example of the improvement in corrosion behavior of weathering steels in an industrial environment is shown in Fig. 7 (see also the article "Corrosion of Weathering Steels," *ASM Handbook*, Volume 13B).

Although such behavior is valuable, it must be recognized that it will be observed only under certain circumstances. Interestingly, the improvement is generally best in an industrially polluted environment; less improvement is noted in environments containing chloride—for example, marine environments. Also, the film or patina must undergo repeated wetting and drying to develop. Use of weathering steel in a structure

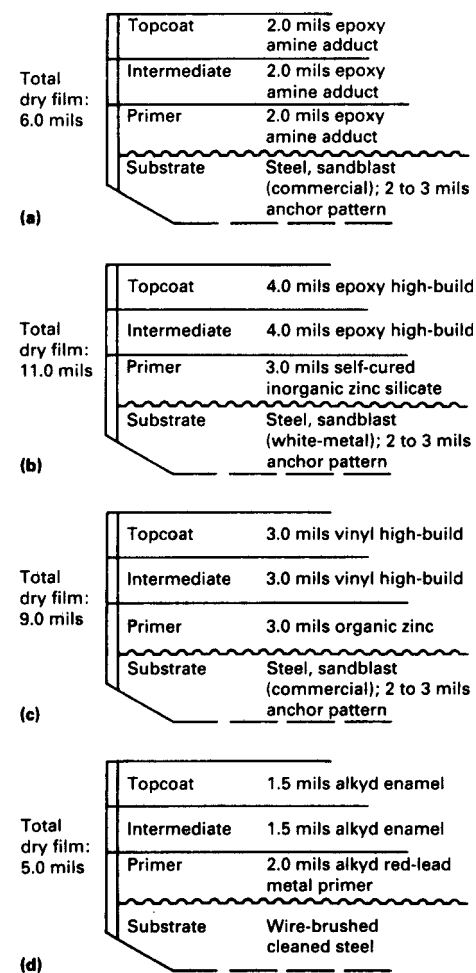

Fig. 5 Typical coating systems used in various environments. (a) Adduct-cured epoxy for use in exposure to solvent spillage and alkaline dust. (b) Inorganic zinc-epoxy used for severe marine exposures. (c) Inorganic zinc/vinyl coating system for use in mild industrial environments. (d) Alkyd-base coating for mild inland atmospheric exposure. Source: Ref 5

where this type of exposure is not available will not allow the protective oxide to form. It is vital to adhere to good corrosion-resistant design techniques when using weathering steels to ensure that the steel performs adequately. Any design or fabrication detail that incorporates crevices, improperly bolted connections, and so on, will lead to behavior in which weathering steels exhibit no advantage over other steels.

Stainless Steels. The ultimate use of alloying elements to promote a barrier layer on the steel surface involves the introduction of sufficient chromium into the steel to form a stable chrome oxide. Stainless steels contain a minimum of 12% Cr and are highly resistant to normal atmospheric conditions. More highly alloyed steels may be required for resistance to severe marine environments. However, the high cost of these materials argues against their use except in critical situations. Such critical situations may, for example, arise in connection bolts, ties, and other components that must perform for the expected service life of the building and are usually not located where inspection, maintenance, or replacement can be easily carried out. Under these circumstances, the use of stainless steel becomes a highly advantageous proposition.

Protection Methods for Cementitious Systems

Cementitious systems normally provide a protective environment to steel. Indeed, the longevity of reinforced steel structures supports this situation. The major factors that cause steel embedded in cementitious systems to corrode are the influences of carbonation and chloride infiltration. Under both of these circumstances, the normally protective oxide film on steel breaks down, and corrosion will proceed at a rate that is sufficient to cause loss of cross section, buildup of voluminous corrosion product with resultant spalling of overlying material and in specific cases, hydrogen embrittlement.

Concrete Covers. One of the principal methods of preventing these problems has been to place cover concrete of sufficient quality and thickness over the steel to dramatically reduce any infiltration of chloride or CO_2 to the steel surface. Because of the diffusion-controlled nature of this infiltration, the depth and permeability of the material have a significant effect on the time at which sufficient chloride or CO_2 reaches the steel surface to allow corrosion to initiate and propagate. The first step in prevent-

ing reinforcing steel corrosion is to ensure adequate concrete depth (typically 50 mm, or 2 in.) over the steel and to use as low a water-to-cement ratio as feasible to promote impermeability within the concrete.

Protection Against Chloride-Induced Corrosion. Although this approach may be adequate to reduce carbonation problems, it may not be sufficient to mitigate chloride-induced corrosion. The reasons are twofold. First, the chloride may have been added to the concrete mix; therefore, it would already be present at the depth of the reinforcing steel, regardless of type, quality, or depth of concrete cover. Such problems can be prevented at the specification stage. The use of chloride-containing admixtures for any purpose should be prohibited. Research has shown that prestressing steel may be even more deleteriously affected by chloride-induced corrosion than conventional reinforcing steel. Limits can be placed on the amount of chloride permissible within the concrete from any source. Therefore, chloride-bearing aggregate could have a considerable influence on this situation.

In the case of marine environments, and particularly in the application of deicing salt, it becomes difficult to ensure that the depth of cover concrete will protect the steel against chloride-induced corrosion attack for the expected life of the structure. Hence, alternative measures become appropriate. These include the application of a barrier coating to the steel or to the concrete surface, or the application of cathodic protection to the steel, generally at a point in the structure life at which corrosion damage has already begun.

Use of Stainless Steels. There has recently been increased interest in the use of austenitic stainless steels as reinforcement in concrete where exposure to chloride, either from marine sources or deicing salt, is foreseeable. The rationale here is a "first cost versus maintenance cost" issue. The assumption is that the stainless rebar will be immune to chloride attack. Testing has been performed on both solid stainless bars and on stainless-clad carbon steel bars. The influence of the molybdenum-containing varieties such as type 316 in improving pitting resistance has been evaluated. Concerns regarding possible

Fig. 6 Effect of zinc coating weight on service life of galvanized steel sheet in various environments. Service life is measured in years to the first appearance of significant rusting.

Fig. 7 Corrosion of three types of steels in an industrial atmosphere. Shaded areas indicate range for individual specimens.

stress-corrosion cracking do not appear to be great as structure temperatures are generally unlikely to approach those necessary for the problem to develop.

Studies by the Oregon Department of Transportation have found that the project cost increases approximately 10% when type 316 is used rather than steel bar, with the benefit that the bridge will last many times longer with no maintenance related to corrosion and no cathodic protection or other corrosion-prevention strategies needed. It is important that the stainless steel used has a chloride corrosion threshold above that expected. With this in mind, a bridge using UNS S32205 stainless steel constructed in 2003 near Coos Bay, OR, is expected to last 120 years.

Use of Protective Coatings. Various coatings for carbon steel in reinforced concrete structures have been evaluated. These can generally be grouped into either organic coatings and inorganic or metallic coatings. Extensive work has demonstrated that the alkaline nature of concrete and the intrusion of chloride into the concrete can be resisted by an epoxy coating on the steel. The reinforcing steel must be carefully prepared prior to application of the coating, and the application method is critical, typically an electrostatic powder spray, followed by baking to fuse the coating (fusion-bonded epoxy, or FBE). Epoxy coated bars have been used in bridge decks since 1973.

Epoxy coatings have been viewed with some disfavor on the basis of bond strength, that is, the tendency of the coating to prevent adequate bond development by lessening adhesion at the deformation/concrete interface. However, it would appear that recommended coating thicknesses, which are typically 0.18 ± 0.05 mm (7 ± 2 mils), mitigate this problem and do not lead to a significant reduction in bond strength.

Additional concerns when using epoxy coatings include the possibility that small holidays in the coating may be subject to accelerated attack, particularly if epoxy-coated steel is used only in the top mat of the structure, and that bare steel is used in the bottom mat. This is a traditional construction method for bridge decks and roadbeds when deicing salt is applied to the top surface; the bare steel at the bottom is rarely exposed to any chloride, because of the large distance (up to 250 mm, or 10 in.) from the upper surface of the concrete to the level of the lower mat. Although it is not clear that this concern has been completely eliminated, testing has indicated that it may not be a major problem. In any case, such a problem could of course be largely eliminated through the use of epoxy-coated reinforcing steel throughout the entire structure. The use of fusion-bonded epoxy reinforcing bar is widely specified.

Metallic coatings for steel in cementitious materials are typically limited to zinc and nickel, while cadmium plate is slightly more resistant to chloride attack than zinc because of the formation of a basic cadmium chloride. The environmental concerns regarding cadmium mitigate against its use.

The most common coating for steel in contact with cementitious materials is zinc applied by hot-dip galvanizing, thermal spraying, or electroplating. The factors that determine the rate at which zinc and zinc-coated steel corrode in cementitious materials are directly linked to the formation and preservation of protective films. A stable film and, therefore, low zinc corrosion rates occurs in the pH range of 6 to 12.5.

Figure 8 shows the influence of pH on the corrosion rate of zinc. It is interesting that the pH of concrete or mortar in the noncarbonated state is typically about 12.5, which is the minimum on the pH versus corrosion rate curve for zinc. This observation is supported by laboratory studies evaluating the corrosion rate of zinc. Therefore, for a noncarbonated mortar, the corrosion rate of zinc in contact with this mortar is effectively 0. Once carbonation occurs, and the pH falls below 10, then the corrosion rate increases—typically to a level of approximately 0.5 to 0.8 $\mu\text{m}/\text{yr}$ (0.02 to 0.03 mils/yr). The use of hot-dip galvanizing as a protective measure for steel exposed to carbonated concrete or, more particularly, mortar is well founded. A typical 64 μm (2.5 mil) galvanized coating would be expected to last more than 80 years under these circumstances.

Zinc does not perform as well when chloride is present in the cementitious material. The use of zinc coatings under these circumstances has been the subject of much debate. Indeed, the results of laboratory testing seem to be in disagreement with studies of large-scale structures that have been fabricated with galvanized steel. Some of these structures are bridge decks in the Caribbean, where no cracking of the structure was noted even after chloride levels of approximately 0.26% by weight of the concrete were present at the concrete/rebar interface. In this case, however, approximately one-tenth of the original galvanized coating had been removed, and further corrosion could be anticipated. In other locations where galvanized steel has been used in bridge decks, no reports are currently known in the open literature reporting the performance of such steel compared to bare steel in the same type of environment.

Studies of reinforced concrete specimens containing galvanized steel, exposed to marine environments and to artificial ponding in CaCl_2 solution, have led to a variety of conclusions related to the effectiveness of galvanizing. They range from a supposedly accelerated cracking of concrete containing galvanized steel to a retardation of such cracking compared with bare steel. However, it should be emphasized that in most of these studies, cracking of the overlying concrete had occurred, indicating that galvanizing is at best a palliative coating for steel in chloride-contaminated cementitious materials.

As far as is known, there is no direct evidence regarding the ability of galvanized steel to withstand a certain level of chloride before significant corrosion can occur. In studies using electrical resistance probes, it was found that, for chloride added to mortar during the mixing phase, the corrosion rate of zinc was of the order

of 0.5 $\mu\text{m}/\text{yr}$ (0.02 mils/yr) for a chloride content of approximately 0.15% by weight of the mortar. In the presence of carbonation, this corrosion rate increased to 10 $\mu\text{m}/\text{yr}$ (0.4 mils/yr). Thus, for a galvanized coating approximately 64 μm (2.5 mils) thick, the coating would survive for only 6.5 years in the presence of carbonation.

Zinc hydroxychloride has been found to form during the corrosion of zinc in chloride-contaminated cementitious materials. This component is significantly expansive compared to the zinc from which it was produced and can therefore cause cracking of overlying cementitious materials even before corrosion of substrate steel has occurred.

Therefore, in general, although zinc-coated steel is somewhat more resistant to chloride-induced corrosion than bare steel, the zinc cannot be relied on to provide protection indefinitely. Indeed, the products of corrosion of the zinc itself may lead to cracking of the overlying material.

In addition to applying barrier coatings on the embedded steel to resist corrosion, a similar barrier surface may be applied to the concrete or masonry surface to resist the penetration of constituents contributing to corrosion. These generally take the form of physical barriers, including:

- Organic membranes applied to the concrete surface (often used on parking structures)
- Low-permeability cementitious-base overlays and repairs (incorporating latex)

Fig. 8 Corrosion of zinc in aqueous solutions as a function of pH

- Polymer impregnation of the concrete (rarely used)
- Waterproofing agents, for example, drying oils, stearates, or silanes

In using one of these systems, care must be taken not to trap the corrosive environment within the structure. Silanes applied to surfaces are effective in preventing this action; they allow water vapor transmission out of the structure but no liquid penetration into the structure. This prevents oxygen transport to the steel while allowing the structure to dry.

Cathodic Protection. Another established method of protection for steel in cementitious materials subject to corrosion is cathodic protection. Cathodic protection is a means of preventing corrosion in a variety of environments, particularly for pipelines and other structures buried in soil or immersed in seawater. It has successfully been used to ensure the protection of steel pipelines and steel reinforcements that are encased in concrete.

Cathodic protection was first applied to the problem of deterioration of conventionally reinforced concrete structures in California. During early experiments, a total surface anode over the entire structure was used to protect the structure. Using this technique, large decks could be protected with only 10 W of power. The surface anode method did, however, require the embedment of current supply anodes in a relatively soft overlay composed of coke-asphalt mix, which itself could be subject to fairly rapid deterioration by traffic. This technique has been used by others with some success, and it continues to be improved.

One of the more important developments in the cathodic protection of structures is the use of anode systems that allow horizontal surfaces other than upward facing to be protected. The development of anode systems incorporating conductive polymers, conductive paints, and conductive concrete (containing typically coke or graphite) has made possible the cathodic protection of the underside of reinforced concrete structures. Examples of such cathodic protection systems are discussed in the article "Cathodic Protection," *ASM Handbook*, Volume 13A.

Impressed-current systems using platinized wires in slots in the concrete surface, surrounded by conductive grout, have been used. Experience with this system has been clouded because of the deterioration of the grout and surrounding concrete by the low pH developed at the anode and by the poor throwing power of the anode. Studies have also been conducted on galvanic (sacrificial anode) systems. In this type of system, for example, zinc wires are placed in slots above reinforcing steel, and the sacrificial action of the zinc is then transferred to the steel directly below.

Some additional observations can be made with regard to the cathodic protection of reinforced steel in concrete. First, care must be exercised whenever cathodic protection systems are considered for application to high-strength

steels, such as those used in posttensioning and prestressing systems because of the susceptibility of these steels to hydrogen embrittlement.

Furthermore, unbonded steel-concrete systems are expected to be difficult to protect because of the possible insulating effects of the sheath that is present around the steel. Indeed, even if such unbonded systems could be protected, the poor throwing power due to the lack of contact between the posttensioning steel and the surrounding concrete is probably an insurmountable problem.

Finally, considerable attention is currently being given to the appropriate criteria for cathodic protection of steel in cementitious materials. Although a transfer of the usual protection criteria from, for example, pipe in soil systems has been made, there is some doubt as to the reasonability or, in some cases, the adequacy of such protection criteria. This is due to the different nature of the environment between concrete and soil, particularly as it relates to pH. Therefore, rather than relying on a -0.85 V versus copper sulfate electrode as a standard criteria for protection, there is more interest in using a potential shift mechanism and in using E -log i plots for establishing the adequacy of the protection.

Case Histories

This section cites specific examples of failures and problems that have occurred within structures to illustrate the general principles discussed previously, to point out those factors that bear most heavily on the development of a particular problem or failure, and to determine how protective or preventive measures can be implemented to repair the structure or to prevent the occurrence of failure in the future. The case history data have been taken primarily from investigations of buildings or structures conducted by the author. Other examples of failures are available in the literature.

Failures Involving Corrosion of Structural Steel

In general, failures related to the corrosion of conventional structural steel (that which has been painted or otherwise protected) are, in the author's experience, rare. Cases do exist in which excessive humidity or chloride-laden water has contacted the metal. The use of weathering steels, however, has caused significant problems, particularly where the necessary design features and environment have not been carefully considered during selection of the material. Two examples of problems involving weathering steels are discussed below.

Example 1: Weathering Steel Corrosion in a Stadium. A large sports stadium situated about 300 m (1000 ft) from the ocean was built with weathering steel in the major structural members. The steel was used not only for the exposed portions of the structure but also beneath the stands. Significant corrosion and rust flaking were noted on this steel at several locations:

- Underneath the stands, where air circulation was poor and wetting/drying cycles could not be anticipated (Fig. 9)
- At sheltered locations on the exterior, again where wetting/drying cycles could not be anticipated (Fig. 10)
- At joint details, where the important concepts of removal of crevices and pockets to retain water had not been practiced in the design of joints for the structure (Fig. 11)

The major problem associated with this structure was the amount of corrosion occurring on the structural steel beneath the stands. Although the loads in these structures were determined to be low, it was apparent that corrosion protection would be necessary. A series of tests was conducted to determine the optimum coating protocol, including surface preparation, type of coating, thickness, and number of coats.

Fig. 9 Heavy buildup of corrosion scale on weathering steel structural members in conditions of poor air circulation, high humidity, and no wetting/drying

Fig. 10 Corrosion scale buildup on weathering steel structural members, which were in a sheltered area on a building exterior where wetting and drying did not occur

This example serves to point out the important factors to be considered by the designer when weathering steel is selected. In particular, the protective patina can be developed adequately only with exposure to weather. Furthermore, marine environments are not conducive to the formation of such a patina, which develops best in an industrial environment with relatively high sulfur levels in the atmosphere.

Example 2: Corrosion of Weathering Steel in a Hotel Parking Garage. A hotel parking garage in the Northeast was constructed with weathering steel in the columns and beams, along with conventional reinforced concrete slabs placed as the decks. The hotel and garage were situated in an area that experienced considerable amounts of snow and freezing temperatures. Deicing salt was commonly applied to roadways adjacent to the structure and was also probably

applied to the reinforced concrete slabs themselves. Severe deterioration was noted in the weathering steel beams and columns, particularly those adjacent to leakage points of water, and in expansion joints. This corrosion was caused by contact with the deicing salt laden water, effectively destroying any patina that would have been expected to develop on the steel. It led instead to the production of voluminous, non-protective oxides.

The failure in this case was caused by a lack of appreciation of the environment to which the weathering steel was to be exposed. Possible solutions to the problem include the use of coatings on the steel to protect it from further contact with chloride-laden water and the correction of water paths that lead to contact with the deicing salt. The sheltered location of most of the steel, however, would not allow effective patina development. Prohibiting the use of chloride deicing salt on the garage decks would probably reduce the problem somewhat, although pickup of deicing salt from roadways

Fig. 11 Heavy corrosion scale buildup on structural members of weathering steel at a pocket where water could collect and stand

Fig. 12 Corrosion-induced spalling of overlying concrete on reinforced columns. See also Fig. 13.

and track-in into the garage is a perpetually unavoidable situation.

Corrosion of Conventional Reinforcement

Corrosion of steel in conventionally reinforced concrete in deicing salt application areas and in marine areas is a well-known phenomenon on bridge decks and bridge support structures. This corrosion phenomenon has received sufficient illustration in the literature and is not repeated here. An example of a similar problem that occurred in a building not subjected to deicing salt or ambient marine environments follows.

Example 3: Corrosion of Reinforcing Steel in Building Columns. Figure 12 shows an example of a supporting column in a dormitory building on a midwestern United States campus. The columns are of conventionally reinforced concrete, with a spiral of reinforcement that closely approaches the surface of the concrete column. The concrete showed cracking and spalling within a few years after its installation. Laboratory examination indicated that the concrete cover was low, that the concrete over the steel was carbonated close to the outer surface, and that the concrete contained a significant amount of chloride, apparently added during construction, that was due to either the presence of chloride-bearing aggregate or the deliberate addition of admixtures such as CaCl_2 . Corrosion of embedded steel was severe in places (Fig. 13).

Because of the likelihood that carbonation might progress into the concrete and, together with the chloride, affect the more deeply embedded steel, the following repair plan was devised. First, loose and spalled concrete was chipped out of the columns. Second, the columns were shotcreted to a depth of approximately 25 mm (1 in.) above the topmost reinforcement. Finally, an impressed-current cathodic protection system was placed on the columns using conductive polymer anodes with integral lead

Fig. 13 Severe corrosion on reinforcing steel from the column shown in Fig. 12

Fig. 14 Unconventional masonry tie constructed from flattened C-channel and bent to enter the brick core

wires. This system was positioned above the surface of the concrete with stands, and the entire system was finally covered with an additional layer of concrete. This minimal concrete removal, along with the subsequent buildup and installation of a cathodic protection system, was far more cost effective than the alternatives, which included complete demolition of the column or removal of sufficient overlying concrete cover to necessitate shoring of the column to support the building above.

Fig. 16 Corrosion and resulting masonry cracking on anchor embedded in high-band mortar. See also Fig. 17

Fig. 15 Severe corrosion and cracking (arrows) on wall tie

Corrosion of Ties and Anchors

The corrosion of steel ties and anchors used to attach masonry walls of the building frame to the backup (usually concrete block) wall, or, more recently, to steel studs, has been a source of significant concern. Cases are known in which such ties or anchors have corroded, either in the mortar or in the airspace. Two examples are given.

Example 4: Corrosion of Nonstandard Wall Ties. In a hospital in the midwest United States, cracking of masonry walls at attachment points to a steel stud backup was observed. When the interior wallboard was removed, the tie between the brick wall and the steel stud was found to be

in the form of a lightweight C-channel that had been flattened and bent to form a 90° angle (Fig. 14). The flattened portion of the anchor was inserted into the masonry bed joint and down into the core of the brick. The remaining, intact portion of the channel was attached to the backup steel stud by a self-tapping screw. No effective corrosion protection had been applied to the angles; they exhibited remnants of shop primer at certain locations, but the efficacy of any coating had been destroyed during the bending and flattening process.

Severe corrosion of these angles had occurred in the airspace adjacent to the brick masonry. This was apparently caused by water running down the interior wall and becoming trapped. Also, the water became trapped in the crevices formed by the flattened channel.

One effect of this corrosion was the interaction with the low cyclic stresses imposed on the tie due to movements between the stud and the wall, leading to cracking of the tie. This was particularly prevalent where corrosion had reduced the tie thickness to a fraction of its original dimension (Fig. 15).

This problem could have been prevented through the use of several alternative techniques, including:

- The use of more conventional ties incorporating corrosion-resistant coatings such as, galvanizing
- The use of heavy organic coatings after bending to prevent corrosion (if this type of tie was to be mandated, then heavy organic coatings applied after bending would have been appropriate)

The solution to this problem could invoke the use of alternative supplementary anchors or the dismantling of portions of the wall containing

Fig. 17 Corrosion and resulting masonry cracking on an anchor embedded in high-band mortar. See also Fig. 16

such ties and replacement with masonry containing more appropriate anchors to ensure continued support of the masonry wall.

In addition to the corrosion of steel in the wall cavity itself, which can generally be lessened by the use of galvanizing, there is also concern regarding the corrosion that may occur in the portion of the tie within the mortar. This is the case where significant chloride is present in the mortar, particularly where chloride and carbonation can interact to produce a corrosive environment. In these cases, the commonly used galvanized thicknesses may not be sufficient to protect the steel over the expected service life of the building.

There have been a number of recent instances where conventional tie corrosion even in the absence of chloride has been sufficiently severe as to impact the safety of veneer brick walls. As

buildings incorporating this system age, further instances of this problem can be expected to develop.

Example 5: Cracking of Masonry Caused by Corrosion of Ties and Anchors. In many structures that have incorporated high-bond masonry mortar additives, the release of Cl^- due to alkaline hydrolysis has significantly corroded uncoated and coated (zinc and cadmium) steel. This has been the case for laid-in-place buildings (utilizing conventional ties) and for panelized buildings (in which embedment of connection devices in the mortar is used to affix the panels to the building frame). In this situation, connection devices may corrode within the mortar, with subsequent cracking of overlying masonry due to the buildup of corrosion product.

Examples of masonry exhibiting such cracking, which radiates from corroded embedded ties

and anchors, are shown in Fig. 16 and 17. Under these circumstances, the integrity of the anchor becomes extremely suspect. No effective method is known for alleviating this problem once it has occurred. Alternative approaches have involved the use of heavily organic coated anchors (for example, epoxy coatings) or the use of austenitic, molybdenum-containing stainless steels, which should resist the onslaught of the Cl^- .

Corrosion of Posttensioning and Prestressing Structures

Unlike other cases of corrosion of steel in structures, the corrosion of posttensioning structures can be troublesome from two viewpoints. First, the possibility exists that substantial corrosion can lead to a loss of cross section and therefore failure of the gripping mechanism for the posttensioning strand or of the posttensioning steel itself. Second, corrosion products on the surface of the material may release sufficient hydrogen to cause hydrogen embrittlement. Two examples are given below.

Example 6: Corrosion of Posttensioning Anchorages. A posttensioned garage in the snow-belt area of the United States exhibited significant corrosion of conventional reinforcement, as noted by the presence of cracking and spalling of overlying concrete. On one occasion, a posttensioning tendon failed. This led to a large-scale investigation of posttensioning members, particularly the anchorages. The anchorages were found to be significantly corroded because of their location adjacent to leaking expansion joints and because they were surrounded by badly consolidated concrete. This had allowed deicing salt to penetrate to the level of the anchorages, leading to some severe corrosion, particularly to gripping wedges, as illustrated in Fig. 18.

Several of the anchorages were sufficiently corroded that alternative anchorages had to be installed. In others, the corrosion was slowed by the injection of water-displacing grease into the anchorage through a grease fitting. This case history shows how poor-quality concrete can significantly affect the performance of metals embedded within it, particularly when the metals are vitally important to the longevity and safety of the structure.

Example 7: Hydrogen Embrittlement of Posttensioning Wires. Single 6.4 mm (0.25 in.) posttensioning wires failed in a parking garage in the southern portion of the United States. A typical anchorage with a broken buttonhead wire is shown in Fig. 19. Several such wires were removed, and the lengths were examined for signs of corrosion. Localized shallow pitting was common, as illustrated in Fig. 20. Chloride was detected in some of these pits.

Scanning electron microscopy and metallography of the ends of the fractures revealed an initial crack that was probably caused by hydrogen embrittlement (Fig. 21). Apparently,

Fig. 18 Corrosion of posttensioning anchorage. Note severe corrosion at the two wedge halves.

Fig. 19 Posttensioning anchorage with broken wire extending from anchor plate

Fig. 20 Pitting corrosion adjacent to fracture on failed posttensioning wire

the hydrogen embrittlement had occurred because of the presence of the corrosion on the external surface. No chloride was detected on the fracture surface, and none was detected in the overlying concrete. This suggested that the corrosion observed may have initiated before placement of the tendons within the concrete. There is no known method of mitigating this type of problem once it has occurred, although it can be prevented through the use of judicious and careful corrosion-preventive techniques during the storage of the tendons before placement.

Corrosion of Metal Processing Equipment

Revised by B. Mishra, Colorado School of Mines

DEVELOPMENT OF METALS AND ALLOYS for novel and advanced commercial applications places higher demands on metal processing to obtain the desired structure and properties, both on the surface and in the bulk. Typically, the bulk properties and structure are developed by compositional control and heat treatment of the component, while superior surface characteristics are developed by metal finishing processes. Heat treatment requires high-temperature equipment, while metal finishing is usually a near-ambient-temperature process. High-temperature furnaces generally are exposed to hot corrosive fluids, mostly gases, while the metal finishing processes expose the process equipment to corrosive acidic and alkaline solutions. Metal processing equipment thus is exposed to numerous corrosive environments and corrosion mechanisms. Heat treating equipment is subject to high-temperature oxidation, carburization and decarburization, and sulfidation, in addition to high-hydrogen and nitrogen-bearing atmospheres. Corrosion by molten salts and molten metals is also a problem for heat treating furnaces and accessories. Equipment for plating, pickling, anodizing, and other chemical and electrolytic processes is exposed to acid and alkali solutions as well as corrosive fumes at temperatures up to or higher than 100 °C (212 °F). Information on materials for and prevention of corrosion in these applications is also available in *Heat Treating*, Volume 4, 1991, and *Surface Engineering*, Volume 5, 1994, of *ASM Handbook*. This article describes the two aspects of metal processing equipment corrosion: heat treating furnace equipment, and plating, anodizing, and pickling equipment.

Corrosion of Heat Treating Furnace Equipment

Heat treating furnace accessories include trays, baskets, pots, blowers, sensors, belts, hangers, bellows, and dampers. Heat treatments include annealing, normalizing, hardening, carburizing, nitriding, carbonitriding, brazing, galvanizing, and sintering. Typically, the furnace accessories and the furnace chamber are exposed to the same corrosive conditions as the parts

being processed. High-temperature furnaces are usually ceramic refractory lined for thermal insulation of the outer metallic shell; the refractory material then is subject to corrosion and erosion damage.

The medium or environment used for heat treating varies from process to process. The high-temperature corrosion performance of furnace components depends on the environment (or atmosphere) involved in the operation. Typical environments are air, combustion atmospheres, carburizing and nitriding atmospheres, molten salts, and protective atmospheres (such as endothermic atmospheres, nitrogen, argon, hydrogen, and vacuum). Protective atmospheres are used to prevent metallic parts from forming heavy oxide scales during heat treatment. The environment can often be contaminated by impurities, which can greatly accelerate corrosion. These contaminants (such as sulfur, vanadium, and sodium) generally come from fuels used for combustion, from fluxes used for specific operations, and from drawing compounds, lubricants, and other substances that are left on the parts to be heat treated. Sodium salts can lead to acid or basic fluxing, resulting in hot corrosion. In oil-fired furnaces, vanadium and sodium cause problems by forming a eutectic mixture. Residual fuel oils contain 1000 ppm vanadium and 10 ppm sodium. At approximately 700 °C (1300 °F), the eutectic of 99% V and 1% Na melts into a viscous, sticky liquid. This liquid slowly corrodes localized areas of equipment (Ref 1).

The high-temperature corrosion processes that are most frequently responsible for the degradation of furnace accessories are oxidation, carburization, decarburization, sulfidation, molten-salt corrosion, and molten-metal corrosion. Each corrosion process, along with the corrosion behavior of important engineering alloys, is discussed in this section. In each case, the corrosion susceptibility of the components is enhanced due to thermal cycling. Thermal cycling not only promotes the loss of protective surface films but also causes structural distortion. The compositions of the alloys under discussion are given in Table 1. Application of high-temperature corrosion and oxidation-resistant coatings has become common for furnace accessories and equipment. These coatings are typically ceramics or thermally densifying

materials applied using physical vapor deposition, plasma, chemical vapor deposition, and high-velocity oxyfuel spray methods (Ref 2).

Oxidation

Oxidation is probably the predominant high-temperature corrosion process encountered in the heat treating industry, owing to the fact that air is the most common heat treating atmosphere for cost reasons. Oxidation involves air or combustion atmospheres with little or no contaminants, such as sulfur, chlorine, alkali metals, and salt.

Carbon steel and alloy steels generally have adequate oxidation resistance for reasonable service lives for furnace accessories at temperatures to 540 °C (1000 °F) (Ref 3). At intermediate temperatures of 540 to 870 °C (1000 to 1600 °F), heat-resistant stainless steels, such as 304, 316, 309, and 446, generally exhibit good oxidation resistance (Ref 3). As the temperature increases above 870 °C (1600 °F), many stainless steels begin to suffer rapid oxidation. Better heat-resistant materials, such as the nickel-base high-performance alloys, and other refractory and nonferrous metal alloys in association with protective coatings are needed for furnace components to combat oxidation at these high temperatures.

Numerous oxidation tests on commercial alloys have been performed at 980 °C (1800 °F) or higher. For example, in one investigation, cyclic oxidation tests were conducted in air, with each cycle consisting of exposing the samples at 980 °C (1800 °F) for 15 min, followed by a 5 min air cooling (Ref 4). The performance ranking, in order of decreasing performance, was found to be as follows: Inconel alloy 600, Incolloy alloy 800, type 310 stainless steel, type 309 stainless steel, type 347 stainless steel, and type 304 stainless steel. Similar cyclic oxidation tests performed in air at 1150, 1205, and 1260 °C (2100, 2200, and 2300 °F), cycling to room temperature by air cooling after every 50 h at temperature, showed Inconel alloy 601 to be the best performer, followed by Inconel alloy 600, and Incolloy alloy 800 (Ref 5).

In another study, ferritic stainless steels such as E-Brite 26-1 and type 446 were shown to be

significantly better than type 310 stainless steel and Incoloy alloy 800H in terms of cyclic oxidation resistance in air (Ref 6). These test results showed weight change data of 2.2 mg/cm² for E-Brite 26-1 stainless steel, 10.0 mg/cm² for type 446 stainless steel, -83.2 mg/cm² for alloy 800, and -90.3 mg/cm² for type 310 stainless steel after exposure of the samples for a total of 1000 h, with 15 min at 980 °C (1800 °F) and 5 min at room temperature. A separate test was also conducted. This test involved exposure of the samples at 980 °C (1800 °F) for 1000 h in

air, with interruptions after 1, 20, 40, 60, 80, 100, 220, 364, and 512 h for cooling to room temperature. The weight change results of these four alloys were -12.9, 9.2, 1.7, and 3.0 mg/cm² for E-Brite 26-1 stainless steel, type 446 stainless steel, type 310 stainless steel, and Incoloy alloy 800, respectively (Ref 6).

An oxidation database for a wide variety of commercial alloys, including stainless steels, Fe-Ni-Cr alloys, Ni-Cr-Fe alloys, and high-performance alloys, was generated (Ref 7). Tests were conducted in air at 980, 1095, 1150,

and 1205 °C (1800, 2000, 2100, and 2200 °F) for 1008 h. The samples were cooled to room temperature once a week (each 168 h) for visual inspection. The results are summarized in Table 2.

Type 304 stainless steel and type 316 stainless steel both exhibited severe oxidation attack at 980 °C (1800 °F), while type 446 stainless steel showed relatively mild attack. Many higher alloys, such as Incoloy alloy 800 and the nickel- and cobalt-base alloys, showed little attack. At 1095 °C (2000 °F), type 446 stainless

steel suffered severe oxidation. Iron-nickel-chromium alloys, such as Incoloy alloy 800H and alloy RA330, also suffered significant oxidation. Many nickel-base alloys, however, still exhibited little oxidation. At 1150 °C (2100 °F), most alloys suffered unacceptable oxidation, with the exception of only a few nickel-base alloys. At 1205 °C (2200 °F), all alloys except Haynes alloy 214 suffered severe attack. Alloy 214 showed negligible oxidation at all the test temperatures. This alloy is different from all of the other alloys tested in that it forms an aluminum oxide (Al₂O₃) scale when heated to elevated temperatures. Other alloys tested form chromium oxide (Cr₂O₃) scales when heated to elevated temperatures.

The alloy performance rankings (Ref 8) generated from the field in the furnace atmosphere produced by the combustion of natural gas were found to correspond closely to the air oxidation data presented in Table 2. The alumina-forming alloy 214 was found to be the best performer (Ref 8).

The high-temperature oxidation resistance of stainless steel as well as aluminum- and silicon-bearing alloys relies on the development of a tenacious, nonporous, and adherent film of chromium oxide, aluminum oxide, and silicon oxide, respectively. Thus, high-temperature metallic coatings developed for oxidation resistance contain these metals. The primary reaction on ferrous material oxidation is given as:

The equilibrium of this reaction is controlled by the activities of the reacting and product species and the temperature. Temperature is also responsible for faster kinetics in these reactions.

Carburization

Materials problems due to carburization are quite common in heat treating components associated with carburizing furnaces. The environment in the carburizing furnace typically has a carbon activity that is significantly higher than that in the alloy of the furnace component. Therefore, carbon is transferred from the environment to the alloy. This results in the carburization of the alloy, and the carburized alloy becomes embrittled. The protective atmosphere is created for oxidation protection; that is, the CO/CO₂ ratio in the furnace atmosphere is maintained high to generate a low oxygen partial pressure:

However, a competing reaction requires that the carbon dioxide activity be high to prevent carbon deposition by the following reaction:

The temperature-dependent competition between these two reactions determines the

sensitivity of the heat treatment furnace accessories to oxidation, carburization, and decarburization.

Nickel-base alloys are generally considered to be more resistant to carburization than stainless steels. The results of 25 h carburization tests performed at 1095 °C (2000 °F) in a gas mixture consisting of 2% methane (CH₄) and 98% hydrogen revealed the weight gain data of 2.78, 5.33, 18.35, and 18.91 mg/cm² for Inconel alloy 600, Incoloy alloy 800, type 310 stainless steel, and type 309 stainless steel, respectively (Ref 9). Extensive carburization tests have been performed to investigate 22 commercial alloys, including stainless steels, Fe-Cr-Ni alloys, Ni-Cr-Fe alloys, and nickel- and cobalt-base alloys (Ref 10). Tests were performed for 215 h at 870 and 925 °C (1600 and 1700 °F) and for 55 h at 980 °C (1800 °F) in a gas mixture consisting of 5 vol% hydrogen, 5 vol% CH₄, 5 vol% carbon monoxide (CO), and the balance argon. It was found that the alumina-forming Haynes alloy 214 was the most resistant to carburization among all of the alloys tested.

These findings were confirmed in 24 h tests performed at 1095 °C (2000 °F) in the same gas mixture. The carburization data are summarized in Table 3. In this study, alloy 214 (an alumina former) was found to be significantly better than the chromia formers tested. Field tests were conducted in a heat treating furnace used for carburizing, carbonitriding, and neutral hardening operations (Ref 11). Both RA333 and Inconel alloy 601 were found to exhibit better carburization resistance than any of the alloys tested, which included RA330 and Incoloy alloy 800. It is evident that alloys containing strong carbide formers, such as stainless steels, or having high permeability for carbon show poor resistance to carburization, while the alloys with weak carbide formers, such as nickel and aluminum, show better resistance.

Metal dusting is another frequently encountered mode of corrosion that is associated with carburizing furnaces. Metal dusting tends to occur in a region where the carbonaceous gas atmosphere becomes stagnant. The alloy normally suffers rapid metal wastage. The corrosion products (or wastage) generally consist of carbon

soots, metal, metal carbides, and metal oxides. The attack is normally initiated from the metal surface that is in contact with the furnace refractory. The furnace components that suffer metal dusting include thermowells, probes, and anchors. Figure 1 illustrates the metal dusting

Fig. 1 Metal dusting of a Multimet alloy component at the refractory interface in a carburizing furnace. (a) Perforation of the component (arrows). (b) Cross section of the sample showing severe pitting. (c) Severe carburization beneath the pitted area

attack on Multimet alloy. The component was perforated as a result of metal dusting. Metal dusting problems have also been reported in petrochemical processing (Ref 12).

Metal dusting has been encountered with straight chromium steels, austenitic stainless steels, and nickel- and cobalt-base alloys. All of

these alloys are chromia formers; that is, they form Cr_2O_3 scales when heated to elevated temperatures. No metal dusting has been reported on the alloy systems that form a much more stable oxide scale, such as Al_2O_3 , because alumina is a much more thermodynamically stable oxide than chromia. The Al_2O_3 scale was found to be much more resistant to carburization attack than the Cr_2O_3 scale (Ref 10). Because metal dusting is a form of carburization, it would appear that alumina formers, such as Haynes alloy 214, would also be more resistant to metal dusting.

Sulfidation

Furnace environments get sulfur from fuels, fluxes used for specific operations, and cutting oil left on the parts to be heat treated, among other sources. Sulfur in the furnace environment could greatly reduce the service lives of components through sulfidation attack.

It is well known that nickel-base alloys are highly susceptible to catastrophic sulfidation due to the formation of nickel-rich sulfides, which melt at approximately 650 °C (1200 °F). Figure 2 illustrates catastrophic failure of a Ni-Cr-Fe alloy tube due to sulfidation attack in a heat treating furnace. The liquid-appearing nickel-rich sulfide phases are clearly visible.

A sulfidation study was undertaken to determine the relative alloy rankings of base alloys (Ref 10). Tests were performed at 760, 870, and 980 °C (1400, 1600, and 1800 °F) for 215 h in a gas mixture consisting of 5% hydrogen, 5% CO , 1% carbon dioxide (CO_2), 0.15% hydrogen sulfide (H_2S), 0.1% H_2O , and the balance argon. The cobalt-base alloys were found to be the best performers, followed by iron-base alloys, and then nickel-base alloys, which, as a group, were generally the worst performers. Among iron-base alloys, the Fe-Ni-Co-Cr alloy 556 was better than Fe-Ni-Cr alloys such as Incoloy alloy 800H and type 310 stainless steel. The test results of representative alloys

from each alloy base group are summarized in Table 4.

Molten-Salt Corrosion

Molten salts are used in the heat treating industry for tempering, annealing, hardening, reheating, carburizing, and other operations. The salts that are commonly used include nitrates, carbonates, borates, cyanides, chlorides, fluorides, and caustics, depending on the operation. For example, a mixture of nitrates and nitrites is normally used for tempering and quenching. An alkali chloride carbonate mixture is used for annealing ferrous and nonferrous metals. Neutral salt baths containing mixed chlorides are used for hardening steel parts.

Carbon steels, alloy steels, stainless steels, and Fe-Ni-Cr alloys have been used for various furnace parts, such as electrodes, thermocouple protection tubes, and pots for salt baths. Molten-salt corrosion of ferrous and nonferrous metals has been reported (Ref 13), showing embrittlement of the alloy via grain-boundary penetration.

Corrosion data in molten sodium-potassium nitrate ($\text{NaNO}_3\text{-KNO}_3$) salts are given in Table 5. The Ni-Cr-Fe-Al-Y alloy (Haynes alloy 214), Ni-Cr-Fe alloys (Inconel alloys 600 and 601), and Ni-Cr-Mo alloys (Hastelloy alloys N and S) performed significantly better than stainless steels and Fe-Ni-Cr alloys such as Incoloy alloy 800H and RA330. The data generated from 1 month tests in a neutral salt bath containing a mixture of barium, potassium, and sodium chlorides (BaCl_2 , KCl , and NaCl) at 845 °C (1550 °F) were reported (Ref 8). The results are summarized in Table 6. Table 7 shows the performance of these alloys in sodium chloride salt (Ref 14).

It was found that the corrosion of a nickel-base alloy salt pot containing molten $\text{BaCl}_2\text{-KCl-NaCl}$ mixture at 1010 °C (1850 °F) was significantly different between the airside (outside of the pot) and the molten-salt side (inside) (Ref 15). The outside of the pot (that is, the air side contaminated with salt vapors) suffered three times as much attack as the inside of the

Fig. 2 Catastrophic sulfidation of an Inconel 601 furnace tube. The furnace atmosphere was contaminated with sulfur; the component failed after less than 1 month at 925 °C (1700 °F). pot, which was in contact with molten salt due to the higher concentration of oxygen on the outside.

Molten-Metal Corrosion

Some heat treating operations involve molten metals. Lead is used as a heat treating medium. Cast iron and carbon steels have been used for components in contact with molten lead at temperatures to 480 °C (900 °F). In a 1242 h test in molten lead in an open crucible at 600 °C (1110 °F), Inconel alloy 600 was not appreciably attacked either at or below the liquid-metal surface (Ref 16). At 675 °C (1250 °F) for 1281 h in molten lead, Inconel alloy 600 suffered severe corrosion attack (Ref 16). Few corrosion data in molten lead have been reported in the literature.

The molten-zinc bath is used for galvanizing processes. Few corrosion data are available in the literature to allow engineers to make an informed materials selection for furnace components in contact with molten zinc. Carbon steel is generally used for the furnace components. Iron-nickel-cobalt-chromium alloys such as Haynes alloy 556 also have been reported for use as baskets. Molten tin is commonly used in the glass industry for solidification.

Corrosion of Plating, Anodizing, and Pickling Equipment

The metal finishing industry uses a wide variety of materials and processes to clean, etch, and plate metallic and nonmetallic surfaces to provide desired surface properties. The equipment is exposed to the same chemicals and fumes as the workpiece that is being finished in the process. The corrosive materials include solvents and surfactants for cleaning, acids and bases for etching and pickling, and solutions of metal salts and other compounds to plate a finish onto a substrate.

Physical, chemical, and electrochemical processes are all used to finish metal workpieces. An electroplating, anodizing, or pickling shop environment is highly corrosive to metals. The metals and alloys used in the construction of equipment to be employed in this environment must be inert to the environment or must be protected from it. While the effect of temperature is not significant in the corrosion of metal finishing equipment, unlike furnace heat treatment equipment, the environments are highly corrosive. However, most common metallic alloys and structural materials can withstand these environments, because they passivate in mildly acidic solutions and most alkaline solutions. Polymeric materials or polymer- and ceramic-coated metallic materials as well as wood and concrete are commonly used for construction of metal finishing equipment. However, stainless steels and carbon steels are also used when the metal can passivate in the solution. Figure 3 shows a typical metal finishing process sequence

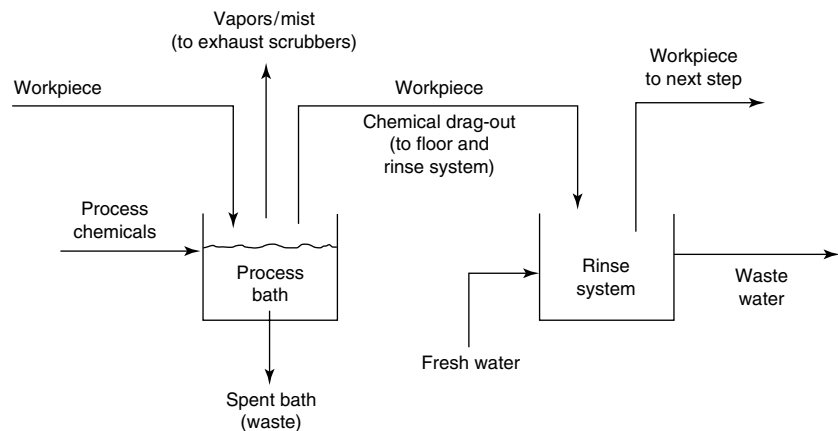

Fig. 3 Typical process sequence in a metal finishing shop. The process bath could be used for plating, anodizing, or pickling

identifying the sources of corrosive waste liquids and gases (Ref 17). These waste streams are not only highly aggressive toward the process equipment but pose significant health and safety hazards for the operator. The toxic and carcinogenic effects of hexavalent chromium baths for hard-chromium plating are well established. The effluent gaseous emissions from typical metal finishing operations are listed in Table 8 with reference to emissions from a hard-chromium plating bath (Ref 18).

Tanks

The common materials for constructing tanks for plating, anodizing, and pickling are carbon steel and stainless steel, usually one of the austenitic (18Cr-8Ni) varieties. Concrete, plastic, wood, and fiberglass, alone or with reinforcing,

also are used. Of these, only the metals offer any serious corrosion problems. The nonmetals, however, must be carefully selected to prevent contamination of the processing solutions. Table 9 recommends tank materials for the various solutions found in the finishing shop. More information on designing the tank to prevent or minimize corrosion is available in the article "Designing to Minimize Corrosion" in *ASM Handbook*, Volume 13A, 2003. Particular attention must be paid to welded areas and other sharp corners where solution may shelter, giving rise to the formation of a corrosion cell and the potential for crevice corrosion.

Corrosion Protection for Steel Tanks. The outside of a carbon steel tank must be protected, regardless of what is contained in the tank. For example, a steel tank containing an alkaline cleaner will not need protection on the inside, because the alkaline cleaner will keep the steel

passivated and at a very low corrosion rate; however, the outside surfaces, which are exposed only to water and the corrosive environment of the shop atmosphere, will corrode severely. Protection of the outside surfaces of corrosion-resistant steel tanks is generally not necessary, except where crevices are possible and oxygen cells can be set up. However, because the tank material is corrosion resistant, overlapping joints are frequently ignored; this provides an initiation site for corrosion.

Protective coatings for the outside of a steel tank should include a good two- or three-coat paint system. Epoxies, vinyls, or polyurethanes can be used. A system that consists of an epoxy primer applied over a clean, sandblasted surface, followed by two coats of a two-part urethane topcoat, will provide adequate protection in a finishing shop environment. Vinyl systems are immune to all solutions except very strong

Table 8 Relative concentrations of uncontrolled atmospheric emissions from various surface coating operations in the electroplating industry

solvents and are excellent coatings for tank surfaces. Vinyl systems are also adequate for the inside surfaces of rinse and holding tanks. Vinyls should be applied only to clean, sandblasted (white metal) surfaces and should be a complete system; that is, primer and topcoat should both come from the same manufacturer and should be matched to each other.

Coal tar and epoxy-modified coal tar systems are excellent tank coatings. These coatings can be used on the inside and outside surfaces of cold tanks, such as rinse tanks. Epoxy-modified coatings tend to soften in contact with hot cleaning, pickling, or plating baths. The epoxy-modified coatings, however, are excellent for tank understructures, such as the I-beams that keep the tanks off the floor and for the floor itself. All of these coatings can be applied also to corrosion-resistant steel tanks, if required. The coal tars and the epoxy-modified coal tars are especially useful as coatings on the bottoms of tanks and between the tank and floor supports, where they are used to prevent crevices in overlapping joints.

Nonmetal liners can also protect the insides of carbon steel tanks used in the metal-finishing industry. Materials for this application are listed in Table 9. Liners that are applied directly to the steel walls (hot melts, Table 9) should offer sufficient protection for the steel. The drop-in liners—whether they are made outside of the tank by molding (or other methods) or are made inside of the tank by welding or adhesive bonding—leave the tank wall unprotected and create an ideal crevice corrosion area. Water and solutions can leak between the liner and the tank. However, a heavy coat (or two light coats) of primer on these steel surfaces will offer sufficient protection so that wetting of the inside of the tank does not become a problem.

The 300- and 400-series stainless steels often use nitric acid/hydrofluoric acid mixed solutions for pickling at approximately 50 °C (120 °F) by dipping for as much as 20 min. These solutions are highly aggressive, because they promote hydrogen embrittlement and hydrogen blistering in carbon steels. Attack of refractory metals is accelerated by hydrofluoric acid in the presence of nitric acid. Thus, tanks for stainless steel pickling require special non-metallic coatings.

Plating-, Anodizing-, and Pickling-Associated Equipment

In addition to tanks, other equipment, such as rectifiers, heaters, pumps, racks, bus bars, and wiring, are subject to corrosion in the environment of the finishing shop. These pieces of equipment do not come in direct contact with the corrosive chemicals but are exposed to an environment loaded with fumes.

Wirings and Bus Bars. Wire terminations, especially bare direct current (dc) terminations, are subject to corrosion. Only copper wire is recommended. Each termination should be

overcoated with grease and inspected regularly. When a corrosion product is seen at a termination, it should be cleaned and reconnected, and the protective grease replaced. For dc connections to bus bars, a lead or lead-tin coating applied to the terminal lugs, the bar, washers, and bolts offers excellent protection. Copper bus bars require constant cleaning not only to remove corrosion products but also to ensure good connections to the rack splines. Tin, lead, and silver coatings on the bars provide temporary protection but do not eliminate the need for cleaning.

Racks. A properly designed rack will have bare areas only in the area of the hook, which is required for contact with the bus bar, and in the area of the tip, which is required to make contact with the part. Both of these areas are subject to corrosion from the shop atmosphere during storage and from the solutions during use. These areas also require constant maintenance. Aluminum and titanium anodizing racks are subject to anodization of the rack tips. Steel or stainless steel is often used as a rack material for carrying the load of the parts being treated—for example, a heavy crank shaft in a chromium plating bath. Both of these materials require complete masking, even where they make connection with the part. The copper current-carrying member of the rack also requires masking. Steels, titanium, and aluminum are commonly used for this application. Their corrosion rates in various corrosive media at different temperatures are shown in Table 10.

Anode splines are generally copper above the plating solution and can be coated with any rack coating, except at the hook where electrical connection is made. Anode splines submerged in the solutions, except those made of the metal that is to dissolve in the bath, must be inert or masked. Rack coatings can be used for this purpose. Inert anodes (that is, those that carry current but do not dissolve), such as titanium in a nickel bath or lead in a chromium bath, are corrosion resistant and require little care. Iron anodes used in an alkaline tin bath, however, are subject to rusting when not in the bath. These units require protection when not in use or require cleaning before use.

Pumps. Conventional metal pumps will corrode in acid solutions. The current trend is to make pumps out of plastic (especially pumps that will be used for small tanks). The body of the pump is usually a grade of phenolic, and the impellers are hard rubber. In this case, the only metal part exposed to the solution is the impeller shaft, which can be fabricated from stainless steel or one of the acid-resistant nickel or cobalt alloys. Metal pumps require constant care to prevent or minimize corrosion.

Heaters. Hot water or steam tank heaters should be treated as part of the boiler system in order to prevent corrosion from the inside. Iron can be used in alkaline solutions, copper can be used in water and neutral solutions, and stainless steel can be used in mildly acid solutions. Stabilized lead can be used in chromic and fluoboric

acid solutions. Carbon and ceramic heat exchangers can be used in all solutions except those containing fluoborates and fluorides. The same is true of immersion ceramic or quartz heaters if the framework is coated.

Corrosion in the Mining and Mineral Industry

Revised by B. Mishra, Colorado School of Mines
J.J. Pak, Hanyang University, Korea

THE EXTRACTION, production, and application of metallic materials and alloys, as well as commercially used minerals, entirely depend on the performance and efficiency of the mining and mineral processing industry. Because this industry is responsible for collecting mineral and ore deposits from earth and physically and chemically separating it from the gangue to upgrade the metallic value, it not only uses heavy equipment, machinery, and tools but also employs chemically aggressive solids and fluids for processing. The mining, mineral-processing, and extractive metallurgy industries are concerned with a wide range of corrosive and erosive media and, therefore, must consider materials selection as the most important approach to corrosion resistance. High-manganese steel in crushing and grinding service, various types of cast (hard) iron grinding balls and mill liners, hardenable and carburized grades of low-alloy steel gears and geared transmissions mining machinery, steel and carbide tools and drills, high-nickel and cobalt hardfacing alloys, stainless steel leaching tanks and pumps, and high-nickel-chromium and titanium alloys for the most severe environments are commonly used. This wide selection of materials and their service lives affect operation cost and productivity that directly impacts the cost of the extracted metal. With the increased mechanization in mines, corrosion problems and material performance become increasingly important to the mining industry and the search for better materials in terms of their performance and costs is still underway (Ref 1–10). Table 1 lists some of the engineering materials that have been used for mining and milling equipment.

Corrosion associated with the mining industry can be characterized as electrochemical attack enhanced by abrasion. All ingredients for corrosion attack are available, including highly conductive water, grinding media, dissimilar materials, oxygen, large pH range, stresses, and the presence of many well-known corrosive species in solution. Mine atmospheres and mine waters are unique in that they vary widely from mine to mine. For example, temperatures have been found to range from approximately 5 to

30 °C (40 to 90 °F) in coal mines and above 40 °C (100 °F) in metal mines. Refrigeration and air conditioning have become necessary for improved working conditions. Humidity levels between 90 and 100% are common. Mine water also varies in mineral content, pH, and corrosivity (Ref 11, 12).

Tables 2 (Ref 13) and 3 (Ref 14) list the contents of some mine waters. These constituents have been found in mines in the United States, Canada, and in other countries, although the amounts can vary. Values of pH range from 2.8 (very acidic) to 12.3 (basic). High values are often the result of the lime content of the cement added to backfill. Chloride ion (Cl^-) values show a wide range (from 5 to 25,000 ppm), and sulfate ion (SO_4^{2-}) values range from 57 to 5100 ppm. Chloride and sulfate are considered to be the most aggressive ions present in mine waters and account for the high corrosivity of most mines.

Important constituents of dissolved colloidal or suspended matter that contribute to the corrosive environment can be classified as dissolved gases, mineral constituents, organic matter, and microbiological organisms (Ref 15). Dissolved oxygen enhances the corrosion process, especially in waters with low pH, but oxygen content can vary widely in mine waters. Oxygen concentration also decreases with increasing temperature. One example of the effect of oxygen on corrosion rate is that aeration with oxygen has been found to increase grinding ball wear by 13 to 16% (Ref 16).

Carbon dioxide (CO_2) in mine water is associated with the carbonate ion (CO_3^{2-}) and the bicarbonate (HCO_3^-) ion content. Calcium bicarbonate ($\text{Ca}(\text{HCO}_3)_2$) is reported to be the predominant source, and magnesium carbonate (MgCO_3) has been found to be a less-active secondary source (Ref 15). Carbon dioxide has little effect on corrosion rate except when pH levels are below 7 where CO_2 can react with water to form a weak acid.

Mineral content of mine water begins with the breakdown of iron sulfide minerals, principally pyrite and marcasite, that are generally

associated with most mineralization species. Oxidation of pyrite produces sulfuric acid (H_2SO_4). Consequently, mine water with pH as low as 2 are produced. The acid water accelerates the breakdown of minerals, increasing the concentration of calcium (Ca^{2+}), magnesium (Mg^{2+}), sodium (Na^+), potassium (K^+), and manganese ions (Mn^{2+}) in mine waters. These corrosion reactions start producing hydrogen that diffuses into the structural steel material reaching a critical concentration for hydrogen embrittlement. This has been shown to lead to stress-corrosion cracking (SCC) of rock bolts in mines (Ref 17).

Anaerobic and aerobic microorganisms are well-known corrosion-producing agents. Principal acid-producing species are *Thiobacillus thiooxydans*, an aerobic species (Ref 15, 18). While these bacterial species are exploited to improve leaching of mineral matters in hard-to-leach ores, their presence oxidizes sulfur or sulfur compounds, producing H_2SO_4 and contributing to the acidity of mine water. Another species of aerobic bacteria, *Ferrobacillus ferro-oxydans*, is associated with the *Thiobacillus* type. When both types of bacteria are present, their synergistic effect has been reported to increase H_2SO_4 production by four times as compared with the production rate when no bacteria are present (Ref 19). Acid mine waters produced by these microorganisms can approach very acidic conditions. Anaerobic microorganisms, such as *Desulfovibrio desulfuricans*, are a sulfate-reducing type and are responsible for rapid corrosion of iron and steel structures (Ref 20). They are found in most soils. As mentioned earlier, they also reduce sulfates and sulfides by using available hydrogen from either organic compounds or aqueous electrolyte at the cathodic interface of metal, producing hydrogen sulfide (H_2S).

High humidity, high ambient temperature, dusts, fumes, breakdown of minerals that form acid mine waters, and microbiological microorganisms all contribute to corrosion and lead to degradation of mining equipment. Examples of the corrosion of principal mining equipment are discussed subsequently.

Table 1 Selection of materials for mining and milling equipment

Application	Environment	Materials
Crushing and grinding Mill liners, grates, and abrasion-resistant plates	Heavy pressure, shock-impact loading Severe gouging, crushing impact and wear, wet (pH 5–8)	Austenitic manganese steels (ASTM A128), 4300 series, ASTM A579 alloy steel, 8600 series Austenitic manganese steels, martensitic chromium-molybdenum white cast iron, martensitic high-chromium white cast iron, martensitic nickel-chromium white iron, martensitic medium-carbon chromium-molybdenum steel, austenitic 6Mn-1Mo steel, pearlitic high-carbon steel, pearlitic white cast iron
Grinding balls (Ref 11, 12)	Severe gouging, crushing impact and wear, wet (pH 6–8)	Pearlitic white cast iron, martensitic white cast iron, forged (0.8% C) steel, 4155, Ni-hard type 1, Ni-hard type 4
Grinding rods (Ref 11, 12)	Severe gouging, crushing impact and wear, wet (pH 6–8)	Heat treated alloy steel, 52100 (UNS G52986), hot-rolled AISI 1095 modified with 1.2% Mn, hot-rolled 1095 with 0.4% Mn
Gearing for mining machinery	Wet, lubricated (pH 5–8) wear, light duty Wet, lubricated (pH 5–8) wear, moderate duty	Carburized 1015, 1020, 1022, 1117, 1118, heat treated 4340, 8645 Carburized 8628, 4620, 4615, or equivalent
Load-haul-dump equipment	Wet, lubricated (pH 5–8) wear, heavy duty Wet (pH 5–8) wear, impact	Carburized 4820, 4320, 2320, or equivalent; nitrided 4340, 4140, 4350, and 2.5% Cr steel 1020, cast carbon steel, cast austenitic manganese steels (ASTM A128), cast ASTM A 579 steel, ASTM A514 steel
Percussion drilling tools Hardfacing	Wear, impact, gouging (pH 6–8) High-impact, wet (pH 6–8) Unlubricated metal-to-metal rolling or sliding Highly abrasive conditions, wet (pH 6–8) Sliding abrasion on cutting edge of drilling tools, wet (pH 6–8) Abrasion at high temperature and/or corrosion	Carburized 4320, 8620, and 9315; quenched-and-tempered 4140 Austenitic manganese steels Self-hardened, air-hardened steels High-carbon high-chromium white cast iron, high-chromium white cast iron Special tungsten- and boron-containing weld deposits High-nickel or high-cobalt weld deposits
Pumps	pH (0–13), abrasants pH (0–13), abrasants pH (0–13), abrasants pH (0–13), abrasants pH (0–13), abrasants pH (0–13), abrasants High-temperature environments	Type 304 or 316 stainless steel, Ni-hard types 1 and 4, 27% Cr white cast irons Low-carbon, high-manganese steels Low-alloy cast iron ACI CD-4MCu ACI CF-3M (low carbon for as-welded corrosion resistance) ACI CN-7M (niobium or titanium for as-welded corrosion resistance) ASTM A484 steel (low carbon for as-welded corrosion resistance) ASTM A743 or A744 nickel-base alloy, grade CZ-100
Flotation cells Paddles Spirals Classifiers blades	Corrosive, pH (0–5) Corrosive, pH (0–5) Abrasive ...	Ni-hard type 1, type 316 stainless steel Fiberglass-reinforced plastic and rubber Ni-hard type 1 Ni-hard type 4
Ore chutes Scrapers	Impact, gouging, abrasion, pH 6–8 Impact loading, gouging, abrasion	Ni-hard, nickel-containing manganese steel Cast ASTM A579 steel, Ni-hard cast iron, hard cast irons
Wire rope Piping Scrubbers	Corrosive-abrasive, pH 2–12 Corrosive-abrasive Off-gas products	Kevlar (E.I. DuPont de Nemours and Co., Wilmington, DE), steel wire rope Type 316 stainless steel, CN-7M, Ni-hard cast irons, rubber covered fiberglass-reinforced plastic High-grade nickel alloys
Chain conveyors	Corrosive-abrasive	Plated (nickel, cadmium, or zinc) steels

Table 2 Analyses of some Canadian mine waters. Values have been converted from grams per liter to parts per million.

An analysis of two old mine shafts in South Africa, which had extensive corrosion problems, has shown that the lateral loads developed by the dynamic interaction between the traveling conveyance and the shaft steelwork can exceed the stress limit of corroded buntion at high hoisting speeds. Repair recommendations are (Ref 21):

- Hoisting speed should not exceed 10 m/s (33 ft/s)
- The limiting residual thickness of buntions is in excess of 5 mm (0.2 in.); otherwise, more comprehensive measurements and a replacement program must be implemented.

Mine Shafts

Mine shafts are among the most important components of the infrastructure in an underground mine because they are used for transporting men and materials to and from the ore body, as well as hoisting the ore to the surface. Shaft steelwork, comprising horizontal buntions and vertical guides, is susceptible to corrosion and mechanical damage (Ref 21). The conveyances that are located in the shaft on guides

run continuously from top to bottom of the shaft. These guides are typically attached to a horizontal grid of beams, commonly referred to as buntions, spaced at intervals of 5 or 6 m (16.4 or 19.7 ft). These form the lifeline of the mine shaft but are susceptible to corrosion damage that results from various sources such as spillage, wet conditions, and poor ventilation. A structural collapse within a shaft, in addition to possible injury or loss of life, could lead to significant production loss.

Wire Rope

Mine shaft depths of 1830 m (6000 ft) are not uncommon. Gold mines in South Africa approach depths of 2285 m (7500 ft) (Ref 22). The hoisting equipment used in these mines, especially ropes, on which lives of personnel depend, is subjected to the corrosive environment of the mines. Although wear is also a factor, corrosion is perhaps the most serious aspect of

mine safety. Corrosion is difficult to evaluate and is a more serious cause of degradation than abrasion (Ref 23). If corrosion is evident, the remaining strength cannot be calculated with safety, nor is there any reasonable way to determine whether the rope is safe except based on the judgment of the inspector. Statistical analysis from the results of rope tests on mine-hoist wire ropes has shown that 66% of the ropes exhibited the greatest strength loss in the half of the ropes nearest the conveyance (Ref 24). This is the portion of the rope that is in contact with the shaft environment during most of its service life.

Replacement of hoist rope is a routine procedure in most mines and is suggested every 18 to 36 months, depending on the mine environment and use (Ref 13, 25). Some regulatory agencies will not allow the use of a shaft rope on which marked corrosion is evident (Ref 23). Adequate service life of hoist rope is economically desirable. Therefore, the composition of present-day hoist rope has been extensively studied. Carbon steel strand wire has competition from such substitute materials as stainless steel (Ref 26) and synthetic fibers (Ref 27). Austenitic stainless steel rope (15.5 to 18.5% Cr and 11 to 13% Ni) is available and has endurance strength of 72 to 83% of that of carbon steel wire. Much can be said for synthetic fiber rope construction. For example, aramid fiber rope has exceptional strength-to-weight ratios, outstanding tension-tension-fatigue performance (Ref 27), and excellent corrosion resistance.

Rock Bolts

Rock bolts provide reinforcement above mine openings such as roadways and roof support in underground mines. More than 120 million rock bolts are used per year in the United States mining industry (Ref 23). The rock bolts are bonded into the rock strata, keeping it together just like the steel in reinforced concrete, and provide a clamping action on the rock. The chemical bolt is the most common rock bolt currently in use (Ref 28). An appropriate hole is drilled, the chemical cartridge and bolt are introduced into the hole, and the bolt is rotated and simultaneously pushed through the chemical cartridge to mix together the resin and catalyst as shown in Fig. 1 (Ref 17). Any failure of a rock bolt is a potential concern. Rock bolts made of medium-carbon steel in a number of design variations are subject to corrosion attack in the mine environment. In sulfide mines, the rock bolts have been reported to fail within 1 year by breaking at a distance of approximately 355 mm (14 in.) inside the drill hole (Ref 13). This rock bolt failure has been related to SCC. Roof falls are associated with such rock bolt failures.

Stress corrosion cracking may occur whenever a highly stressed steel is in the presence of an aggressive environment where hydrogen is produced on the steel surface. This ingress of hydrogen into the steel microstructure leads to hydrogen embrittlement. The stress corrosion

cracks initiate and grow slowly. During this phase that may last for months or years, there may be no indication of any damage. Fast fracture occurs when the stress corrosion crack reaches a critical length, as determined by the applied stress and the fracture toughness of the steel. Reports indicate that the critical crack length can be of the order of only 1 to 1.2 mm (0.04 to 0.05 in.) for rock bolts. Figure 2 shows a typical fracture surface for a rock bolt failed in service by SCC (Ref 17). The most prominent feature is the small thumbnail shaped area on the right side of the fracture indicative of SCC. The rest of the bolt shows a shiny irregular surface. From the examination of fracture surfaces of rock bolts during service by SCC, the following SCC mechanism has been proposed. Hydrogen diffuses into the material, reaching a critical concentration level. The embrittled material allows a crack to propagate through the brittle region. The crack is arrested once it propagates outside the brittle region. Once the new crack is formed, corrosion reactions start producing hydrogen that diffuses into the material, causing further embrittlement and cracking (Ref 17).

Pump and Piping Systems

Corrosion in pump and piping systems is well known in the mining and mineral-processing

Table 3 Analyses of three Ontario mine waters. Values are in parts per million unless otherwise stated.

Source of mine water	Levack Mine (sulfide)	Helen Mine (iron)	Leitch Mine (gold)

industries. Centrifugal slurry pumps are used almost universally to move mixtures of abrasive solids and liquids around wet mineral processing operations. These pumps are generally of rugged construction and allow generous clearances for passage of large solids. Useful pump life in these applications can range from a few weeks to a few years depending on the types of slurries handled. The direct cost of slurry pump wear parts for the mining industry and the associated downtime and labor costs are significant. Reducing these total costs requires a better understanding of pump wear patterns and wear rates (Ref 29).

Because recognition of corrosion type is so important in diagnosing corrosion problems and their prevention, corrosion types are discussed and illustrated in the following sections in this article.

Uniform Corrosion. The most common form of pump corrosion is characterized by uniform attack on the entire exposed surface. Figure 3 shows uniform corrosion on a stainless steel pump impeller that was exposed to 50% phosphoric acid (H_3PO_4) and 10% gypsum pumping fluid for approximately 1 year. Uniform corrosion is predictable and, therefore, allows the incorporation of safety factors in pump and piping design.

Pitting Corrosion. One of the most catastrophic forms of corrosion encountered on pump cases is pitting attack. The relatively stagnant liquid conditions, which exist during the pump operation as well as periods of shutdown, create ideal conditions for pit initiation. Use of dissimilar metals in contact with one another in a corrosive liquid sets up a galvanic potential to accelerate preferential corrosion of the more active metal (Ref 30). Pitting corrosion on a UNS J92900 (Alloy Casting Institute [ACI] CF-8M)

stainless steel casting pump case is illustrated in Fig. 4. This pump case, which was exposed to low pH and high Cl^- concentration, failed after approximately 3 years of service. Methods of preventing pitting failures in pump systems would be to prevent any liquid ingress into the contact between dissimilar metals using O-rings or other suitable seals. The use of a more corrosion-resistant material or coatings may also reduce the problem of pitting corrosion (Ref 30).

Crevice Corrosion. Figure 5 shows crevice corrosion on an ACI CF-8M cast stainless steel pump case that was gasket sealed on the discharge flange. Attack is evident in the region where the gasket was placed. It is important to design mining and milling equipment for easy drainage and cleaning in order to prevent the buildup of stagnant water that will produce concentration cells and lead to crevice corrosion and pitting. Figure 6 illustrates both poor and improved design for avoidance of localized attack. More information on proper design is available in the article "Designing to Minimize Corrosion" in *Corrosion*, Vol 13A, of the *ASM Handbook* (refer to pages 929 to 939).

Erosion-Corrosion. Slurry erosion-corrosion can cause significant materials wastage in pump systems. During mill processing, fluids consisting of particulates in a corrosive medium are usually pumped. Pumping this slurry promotes erosion-corrosion in piping, tanks, and pumps. Erosion-corrosion is a function of the fluid velocity and the nature of the particulates and fluid. Erosion-corrosion of a UNS N08007 (ACI CN-7M) stainless steel cast impeller after exposure to hot concentrated H_2SO_4 with solids present is shown in Fig. 7. Erosion-corrosion is also evident in Fig. 8, which shows that the

erosion-corrosion damage increased on the portion of the impeller that had the greatest fluid velocity. This impeller, cast from an abrasion-resistant white iron, was used to pump fluids containing 30% solids (iron ore tailings) at a pH of 11.2.

The following procedures can be used to reduce erosion-corrosion or to increase the service lives of piping and pumping systems:

- Increase the thickness of pipes
- Use larger inside diameter pipes to reduce fluid velocity for the transport of a specific fluid volume
- Streamline bends in piping to ensure laminar flow
- Use nonmetallic ferrules inserted in the inlet ends of pipes

Materials selection is an important consideration for erosion-corrosion resistance. Alloy hardness has also been shown to be a factor in erosion-corrosion resistance. Generally, soft alloys are more susceptible to erosion-corrosion than their harder counterparts, but the relative hardness properties of the alloy can be misleading because the hardening mechanism affects resistance to erosion-corrosion (Ref 11). For example, solid-solution hardening has been found to offer greater resistance than that provided by conventional heat treatment. One example of this is the cast precipitation-hardening alloy UNS J93370 (ACI CD-4MCu), which outperforms UNS N08007 (Alloy 20 [CN-7M]) and austenitic stainless steels in many applications. Economics often enters into materials selection. Cast iron is relatively more economical and frequently exhibits better erosion-corrosion resistance than cast steel. High-silicon cast iron (14.5% Si) has been found to be an economical selection.

Active-passive materials, such as stainless steels and titanium, owe their corrosion resistance to their ability to develop a protective passive oxide film. This protective film, however, can be continuously damaged by erosive-abrasive processes. Damage of this protective film is a required condition for the loss of localized corrosion resistance. Selection of passive alloys should be based only on experience and/or laboratory test results.

Joints must be reliable. Welded pipe, such as carbon steel or stainless steel, is free of flanges but is costly to install. Nonwelded joints are susceptible to crevice corrosion; therefore, stainless steel, in particular, will not attain its expected service life. Recent development of materials with optimum erosion and erosion-corrosion properties and their evaluation techniques are available elsewhere (Ref 1–4, 29, 33–34).

Intergranular corrosion is common to stainless steel pump castings. Figure 9 shows the excessively attacked grain boundaries. A quick test to identify this type of corrosion is to peen

the pump casting with a small hammer. Loss of acoustical properties is evidence of intergranular grain-boundary attack, especially in sensitized stainless steel castings. A form of intergranular corrosion associated with weld deposits that is commonly called weld decay, is shown in Fig. 10, which illustrates a field-weld repair of an ACI CN-7M stainless steel impeller that was not postweld heat treated (solution annealed and quenched) to restore corrosion resistance. This weld-repaired casting was exposed to a phosphoric anhydride (P₂O₅) solution at 80 °C (175 °F). It is evident that the weld decay occurred in the heat affected zone of the weld deposit.

Galvanic corrosion between two stainless steels is illustrated in Fig. 11. These AISI type 304 stainless steel stud bolts held together an Alloy 20 (ACI CN-7M) pump housing. The bolts became anodic to the housing in 45% H₂SO₄ and subsequently failed. Table 4 lists various combinations of pump and valve trim materials and indicates the combination that may be susceptible to galvanic attack. The basic rule for materials selection is that two alloy systems that

Alloy 20	Unsatisfactory	Neutral	May vary(b)

(a) Bronze trim commonly used. Trim may become anodic to body if velocity and turbulence keep stable protective film from forming on seat.
(b) Type 316 is so close to nickel-copper alloy in potential that it does not receive enough cathodic protection to protect it from pitting under low-velocity and crevice conditions. Source: Ref 35

are the most widely apart on this list in terms of the galvanic series should be avoided.

Tanks

Most tanks are made from low-carbon steel for economic considerations. The most common corrosion protection for these tanks is the use of coatings and linings. Cathodic protection can also be used and is commonly employed in conjunction with a coating (Ref 32). Coating materials can be classified as cement, epoxy, epoxy-phenolic, neoprene, latex, sprayed poly-resin coating, polyesters and vinyl esters (heavy coatings), and baked phenolic. Steel tanks are also lined with natural rubber, synthetic elastomers, rubber-backed polypropylene, and glass. Glass lining would require an oven bake.

Stainless steel and titanium alloys have also been used for tanks. Their use depends on their specific corrosion resistance to the solution. Selection of an alloy type becomes a question of economics.

Reactor Vessels

A variety of materials are used, depending on the corrosivity of the media being contained. With neutral or alkaline pH, carbon steels are often used. With increasing corrosivity, consideration is first given to the austenitic stainless steels; then iron-nickel-chromium superalloys; and finally, nickel-base superalloys. For special environments, copper, copper-nickel, and nickel-copper (Monel-type) alloys are used (Ref 36). Titanium is known to have excellent corrosion resistance in some of the most aggressive solutions.

Cyclic Loading Machinery

The mining and mineral industry uses large numbers of rotary and cyclic loaded equipment. This equipment is subject to fatigue and corrosion fatigue. Table 5 illustrates the significant reduction of fatigue strength of various materials that were tested in mine water and compared with fatigue strength in air. This problem can be reduced by designing heavier sections into the part to reduce load and by applying protective coatings (Ref 32).

Corrosion of Pressure Leaching Equipment

Hydrometallurgical applications in mineral processing range from low-tech heap operations to more sophisticated high-pressure leaching processes performed in autoclaves. The temperatures are approximately 260 °C (500 °F) and the pressures approximate 5 MPa (725 psi) in an acidic environment when leaching nickel laterite ores. Acid leaching or high-pressure acid leaching (HPAL) has become the commercial alternative for copper, gold, nickel, uranium, molybdenum, zinc, and other metals extraction (Ref 37). The aggressive acid environments in these pressure leaching operations present serious corrosion problems for the containment materials. While heap leaching can be performed using polymeric or other nonmetallic materials, a high-pressure and high-temperature process requires a metallic- or a ceramic-lined metallic container as the autoclave. Besides the acid environment, presence of oxygen and the multivalent metal ions in the ore solutions create an environment that can be handled by few metallic alloys. Titanium alloys are typically used for HPAL autoclaves. When large tank sizes are required, making titanium prohibitively expensive, titanium clad steel tanks are employed. Explosion cladding of titanium to steel is often the used practice. Grade 17 Ti clad to SA 517 Grade 70 carbon steel performs well (Ref 37). Grades 11, 12, and 17 titanium provide excellent crevice corrosion resistance. Components such as agitator blades may be produced out of Grade 18 titanium (Ref 38). It has been shown that the oxide film exposed to high-temperature acid is significantly greater on Grade Ti-12 than on Grade Ti-18. Highly abrasion-resistant alloys, such as Grade Ti-5 or 12, can be used in severe abrasion and erosion environments. When a potential ignition condition is anticipated due to oxygen impingement or rubbing surfaces, Ti-45Nb alloy may be used that can provide ignition resistance (Ref 37).

Another alloy, UNS N06110 (known as Allcorr, Allegheny Ludlum, Pittsburgh, PA), has also worked well in HPAL environments. In a test under 11 mol% H₂S, 19 mol% CO₂ elemental sulfur, and chloride, at 213 °C (415 °F) and at 69 MPa (10 ksi) pressure, for evaluation of localized corrosion and environmental cracking resistance, Allcorr produced

excellent resistance to environmental cracking and corrosion. Allcorr alloy is a nickel-base alloy containing 27.0 to 33% Cr, 8.0 to 12.0% Mo, and 4.0% (max) W. The very high chromium content allows the alloy to be exposed to very highly oxidizing environments without degradation. The molybdenum and tungsten help resist high-chloride environments and low pH conditions (Ref 39).

Summary

All forms of corrosion, including microbial attack, are found in mining and mineral processing equipment and machinery. Carbon and alloy steels are the most common materials used for these applications. Corrosion protection through superior materials is achieved when it can be economically justified. General corrosion protection is derived by the application of coatings and cathodic protection.

ACKNOWLEDGMENT

This article has been revised from the previously published article, "Corrosion in the Mineral Industry" in *Corrosion*, Vol 13, *Metals Handbook*, 9th ed., ASM International, 1987, p 1293–1298. The authors thank G.A. Minick and D.L. Olson, the authors of the previous article.

Selected Color Images

THE INFORMATION provided by the authors for this Handbook included a great collection of color images. These color figures aid in the identification and classification of forms of corrosion. Naturally, the negative aspects of corrosion have been emphasized. The cost and the great effort to test, evaluate, simulate, and prevent corrosion have been examined. The ability of corrosion to undo our best complex engineered systems has been documented. While the pragmatic use of these images is the focus, you may also wish to consider the aesthetic beauty of some of these corrosion forms.

Fundamentals of Corrosion

In Volume 13A, *Corrosion: Fundamentals, Testing, and Protection*, the fundamentals were presented. The process of material degradation called corrosion generally involves an electrochemical reaction with the movement of electrons and metal ions. In electrical and electronic systems, the imposed electric potential can exacerbate the corrosion process in what may appear to be an otherwise benign environment. This shows evidence of the electrical nature of corrosion. In Fig. 1, copper on a printed circuit board has migrated. In Fig. 2, tin from a soldered terminal formed metal dendrites in the area of highest electrical potential to an adjacent terminal and caused an electrical short circuit. In a flip-chip resistor (Fig. 3), silver has migrated through a ceramic substrate, creating the familiar dendritic pattern. In Fig. 4(a), the metallized capacitor film appears with few faults, while in Fig. 4(b), a visually interesting pattern from a failed capacitor appears.

The internal components of a capacitor show the effect of polarity (Fig. 5). At the terminal marked positive (+), metal is being oxidized and corrosion products are being produced (an anodic reaction site for the galvanic cell), while the foil attached to the terminal marked negative (−) is protected and is cathodic to the corrosion cell.

The principle of cathodic protection, where the object to be protected is made electrically negative or cathodic, has been a tool for preventing or at least reducing corrosion of large

structures such as bridges, piers, ships, and buried pipelines.

Evaluation of Corrosion Protection Methods

Besides manipulating the electric nature of corrosion to advantage, other methods of corrosion protection provide a barrier between the environment and the material to be protected. In Volume 13B, *Corrosion: Materials*, the selection of materials appropriate for the design environments was emphasized. Evaluating how well materials selection and the choice of protection schemes are performing can be done by inspection, testing, and surveys of the actual in-service object, or it may be done through testing of specimens in actual or simulated environments.

A very straightforward approach to atmospheric corrosion testing is to place specimens in natural environments. The testing at Kure Beach, NC, in a coastal marine environment is classic (Fig. 6). The test site at Newport, OR, also collects precipitation runoff samples and quantifies the effect of pollutants and precipitation on the corrosion process (Fig. 7).

The benefits of painting and flame and arc spraying are compared for scribed steel specimens in Fig. 8 after 3.5 years in a severe marine environment.

Microscopic examination of an aluminum laminate (Fig. 9) shows that the protective cladding, while attacked on the left, still protected the inner core. Here, the environment was aviation fuel.

Simulated testing of components allows the effects of corrosion to be accelerated and the function of the component to be checked. In a salt spray corrosion test, the benefit of a corrosion-inhibiting lubricant on a limit switch (Fig. 10a) is compared to an untreated control sample (Fig. 10b).

Forms of Corrosion in Industries and Environments

In this Volume, it is evident that the unique material demands of various industries, the envi-

ronments in which they operate, and the environments they create all contribute to the forms of corrosion that are manifested.

Aviation. In military and commercial aviation, high-strength aluminum alloys in the aircraft must be maintained. Exfoliation corrosion of aluminum is seen in a military cockpit (Fig. 11) and, in a commercial aircraft (Fig. 12a). This figure also presents microbiologically induced corrosion associated with jet fuel (Fig. 12b) and galvanic corrosion (Fig. 12c, d). Because aircraft are a complex combination of many materials, galvanic corrosion is a ubiquitous threat (Fig. 13). Constant vigilance is required in design and manufacturing processes. Silicone sealant, which solved a crevice corrosion problem, can cause the loss of a protective coating (Fig. 14).

The extreme environments in which aircraft exist, from the subfreezing temperatures at altitude to the high-temperature engine gases, and the cyclic changes that occur in every flight pose severe design challenges. Corrosion may be personified as cruel when it appears in the seemingly mild confines of a package at ground level (Fig. 15).

Underinsulation Corrosion. Similar to the corrosion taking place due to improper packaging (Fig. 15), trapped moisture under insulation has been of increasing concern in piping systems (Fig. 16) and storage tanks (Fig. 17).

Art and Artifacts. The apparently mild environments in which art is located provides striking forms of corrosion. The museum atmosphere causes corrosion damage and added unwanted color to the handle of a 2500 year old bronze vessel (Fig. 18).

The bronze hand holding an iron staff forms a galvanic couple in an outdoor statue (Fig. 19). The velvetlike corrosion on an ancient copper alloy vessel (Fig. 20) was found to be a dendritic copper sulfide (Fig. 21). Another collection of dendrites in a museum environment is the silver sulfide crystals on a Greco-Roman silver bowl (Fig. 22).

Automobiles. Improvement in automobile bodies has been a beneficial application of corrosion prevention technology. Examples of corrosion are still found in vehicles, however. The use of dissimilar metals results in the galvanic corrosion of the carbon steel hanger

welded to the stainless steel end bracket of the muffler after less than two years of service, although because of its size, the function is not yet jeopardized (Fig. 23). In a radiator, solder bloom has interfered with the ability to remove heat from the engine (Fig. 24). Another form of corrosion evident in a radiator is erosion-corrosion where the fluid removes the passive film, accelerating the rate of corrosion in high-flow areas such as opposite an inlet (Fig. 25a) and at a tube constriction (Fig. 25b). Another form of mechanically assisted corrosion, cavitation corrosion, is possible in an engine block (Fig. 26) where exhaust gases cause the coolant to boil.

Fossil Fuel Power Plants. With a goal of higher efficiency, engineers are striving to operate the energy conversion equipment at higher temperatures. Materials selection, materials engineering, and surface engineering technologies play a role in protecting components from high-temperature corrosion and in maintaining mechanical strength at these elevated temperatures. The tip of an industrial gas turbine blade (Fig. 27) is subjected to a combination of environmental and mechanical stress. High-temperature oxidation can be protective or not, depending on the oxide growth rate. The tip has oxidized, depleting the surface, while just below, the oxidized coating is protecting the blade. A severely attacked gas turbine blade is seen in Fig. 28. The micrograph (Fig. 29) is of an overlay coating and an aluminide layer that protects the base material of the gas turbine blade from oxidation and hot corrosion.

Steam turbines, boilers, and associated equipment pose challenges to the corrosionist as well. Waterside corrosion in a boiler exhibits layer of

oxides, some porous and some dense. There are needlelike fibrous oxides in one layer and a dispersion of copper particles (Fig. 30) in another. In the same boiler, low-alloy carbon steel was subject to overheating, which resulted in the formation of spheroidal carbides. At three grain junctions, voids formed, grew, and coalesced (Fig. 31).

High-temperature feedwater, 120 to 205 °C (250 to 400 °F), caused flow-assisted corrosion that appeared as a general thinning with a scalloped profile and led to a sudden rupture (Fig. 32).

On the electrical side of a power plant, a water-cooled generator stator faced crevice corrosion in the braze between the rectangular copper wire, as seen through a borescope (Fig. 33). In a high-speed generator, non-magnetic retaining rings made of an 18Mn-5Cr alloy steel must withstand high residual and dynamic stresses. The stress-corrosion cracking that resulted in this now-obsolete material choice is made more evident through fluorescent dye penetrant examination (Fig. 34).

Waste Disposal. Incinerator gases are especially corrosive, and materials selection is critical because the composition of the combustion gas may vary. Nickel-base liners are often used. In the case of an incinerator used by the military aboard ship, the nickel-chromium alloy 690 (UNS N06690) was repaired with a Ni-Co-Cr-Si alloy 160 (UNS N12160) that is known for sulfidation resistance because it forms a silica-rich scale. Figure 35 demonstrates the performance of this material.

Piping and Pipelines. To assure function and safe operation, defects on the millimeter scale must be either prevented or monitored in systems

that can be thousands of kilometers long. For the most part, the systems are buried in walls, under streets, under ground, or underwater. Stress-corrosion cracking of a high-pressure gas pipeline led to its rupture (Fig. 36). The corrosion on the inside of a petroleum pipeline is given the descriptive name mesa corrosion, from the appearance of the wasted wall (lower right, Fig. 37). Another appropriately named corrosion morphology is the tuberculation in a cast iron pipe (Fig. 38).

Piping in a nuclear power plant steam generator unit made of alloy 600 nickel (UNS N06600) was subject to intergranular attack and stress-corrosion cracking at a support location (Fig. 39).

Biomedical Devices. The tolerance for any corrosion or corrosion products in implanted medical devices is very small. The body can be an aggressive environment. In Fig. 40, a Ti-6Al-4V neck and (sectioned) thimble used to attach a ceramic head to the femoral stem were retrieved. The purple tint indicates that Ti^{3+} ions were present, and within the interface it was evident that the pH had dropped below 1. In another case, the head was retrieved from a total hip replacement prosthesis. The Co-Cr-Mo alloy (Fig. 41) shows signs of etching at the dark regions of the inner bowl.

Microbiologically Induced Corrosion. Bacteria and other microorganisms can paint some interesting pictures while inducing corrosion. A microscopic image of stainless steel in seawater reveals a host of microorganisms (Fig. 42). A comparison of aerobic and anaerobic bacteria in seawater is shown in Fig. 43(a to d). The corrosion in a water pipe was induced by sulfate-reducing bacteria (Fig. 44).

Fig. 30 Hotside deposit in the vicinity of the failure displays several layers and waterside oxidation/corrosion. Some layers are dense, while others are very porous. One layer displayed needlelike fibrous oxides. Another layer contains a number of particles of copper metal. Original magnification 210 \times . See the article "High-Temperature Corrosion in Military Systems" in this Volume.

Fig. 31 Waterside surface, hot side, near failure. Carbides in prior pearlite colonies have completely spheroidized from overheating. Creep voids have developed at grain boundaries; some of these voids have grown and coalesced. Original magnification 210 \times . See the article "High-Temperature Corrosion in Military Systems" in this Volume.

Fig. 32 Feedwater pipe thinning and rupture. See the article "Corrosion of Steam- and Water-Side of Boilers" in this Volume.

Fig. 33 Boreoscopic view through bottle clip opening into strand package made of hollow strands that carry cooling water and solid strands that carry the majority of the current. This bundle of copper strands (both hollow and solid) is brazed together into a single, consolidated strand package. Braze material, which is porous, covers the surface of the strands and extends axially back into the coil between strands. It is this material that is susceptible to crevice corrosion cracking as cooling water is trapped in the porous openings and initiates the corrosion process. See the article "Corrosion of Generators" in this Volume.

OD	outside diameter	R_i	internal resistance	TBD	to be determined
OEM	original equipment manufacturer	R_n	noise resistance	TDS	total dissolved solids
OMB	Office of Management and Budget (U.S.)	R_p	polarization resistance	TFE	tetrafluoroethylene
OSHA	Occupational Safety and Health Administration (U.S.)	RAD, rad	radiation absorbed dose	TGA	thermogravimetric analysis
p	page	RBI	risk-based inspection	TGSCC	transgranular stress-corrosion cracking
p	probability of success; partial pressure; pressure	RE	reference electrode; residual element; rare earth element	TOFD	time-of-flight diffraction
P_{O_2}	partial pressure of oxygen	Re	Reynold's number; rhenium	TOW	time of wetness
P	probability	Ref	reference	TSOP	thin-small-outline package
P_a	sensitization number	RF	radio frequency	UNS	Unified Numbering System
Pa	pascal	RH	relative humidity	URL	underground research laboratory; uniform resource locator (web)
PASS	paint adhesion on a scribed surface	rms	root mean square	U.S.	United States
PDF	portable document format	RMU	remote monitoring unit	USAF	United States Air Force
PES	polyether sulfone	rpm	revolutions per minute	USD	United States dollars
PF	pitting factor	s	solid	USDA	United States Department of Agriculture
PFA	perfluoroalkoxy	s	estimate of the standard deviation	UT	ultrasonic testing
PFM	probabilistic fracture mechanics	S	siemen; unit of conductance	UTS	ultimate tensile strength
pH	negative logarithm of hydrogen ion activity	S	entropy	UV	ultraviolet
PHWR	pressurized heavy water reactor	S_a	stress amplitude	ν	viscosity; fluid velocity
PIN	part identification number	S_m	mean stress	V	volt
PP	polypropylene	S_r	fatigue (endurance) limit; stress range	V	volume
ppb	parts per billion	SAE	Society of Automotive Engineers	VNSS	Väätänen nine salts solution
ppm	parts per million	SAN	styrene-acrylonitrile	VOC	volatile organic compound
PPO	polyphenylene oxide	SAW	simulated acidified water	vol%	volume percent
PRE	pitting resistance equivalent	Sc	Schmidt number	w	weight or mass
PREN	pitting resistance equivalent nitrogen (%N is included in formula)	SCC	stress-corrosion cracking	W	watt
PSD	power spectral density	SCE	saturated calomel electrode	WDS	wavelength-dispersive spectroscopy
psi	pounds per square inch	scf	standard cubic foot	WE	working electrode
psia	pounds per square inch (absolute)	scfm	standard cubic feet per minute of gas flow	Wnr	Werkstoff number
		SCR	silicon-controlled rectifier	wt%	weight percent
		SCW	simulated concentrated water (– 1000 times the concentration of J-13 well water)	XLPE	cross-linked polyethylene
		SDW	simulated dilute water	yr	year
		SEM	scanning electron microscopy	YS	yield strength

Z	impedance	$\sqrt{\quad}$	square root of	Ω	ohm
ZRA	zero-resistance ammeter	\sim	similar to; approximately	ω	angular velocity
$^{\circ}$	degree (angular measure)	\propto	varies as; is proportional to	Greek Alphabet	
$^{\circ}\text{C}$	temperature, degrees Celsius (centigrade)	α	chemical activity; crack length; crystal lattice length along the α -axis		
$^{\circ}\text{F}$	temperature, degrees Fahrenheit	β	Tafel coefficient (constant)	A, α	alpha
\rightarrow	chemical reaction	Δ	change in quantity; an increment; a range	B, β	beta
\leftrightarrow	reversible chemical reaction, does not imply equal reaction rates in both directions	ΔE_{therm}	thermodynamic driving force	Γ, γ	gamma
=	equals	ΔG	Gibbs free energy	Δ, δ	delta
\approx	approximately equals	ΔG°	standard Gibbs free energy	E, ϵ	epsilon
\neq	not equal to	ΔH	change in enthalpy	Z, ζ	zeta
$>$	greater than	ΔK	stress-intensity factor range	H, η	eta
\gg	much greater than	ΔS	entropy change	Θ, θ	theta
\geq	greater than or equal to	ϵ_p	plastic strain range	I, ι	iota
\int	integral	ϵ_t	total strain range	K, κ	kappa
$<$	less than	η	overpotential	Λ, λ	lambda
\leq	less than or equal to	μm	micron (micrometer)	M, μ	mu
\pm	maximum deviation; tolerance	ν	kinematic viscosity	N, ν	nu
$-$	minus; negative ion charge	Π	symbol for multiplying a series of terms; pi	Ξ, ξ	xi
\times	multiplied by; diameters (magnification)	π	pi, 3.14159...	O, o	omicron
\cdot	multiplied by	ρ	density	Π, π	pi
$/$	per; divided by	Σ	summation	P, ρ	rho
%	percent	σ, σ'	standard deviation; oxide conductivity; stress	Σ, σ	sigma
$+$	plus; in addition to; positive ion charge	τ_0	time constant	T, τ	tau
		Φ	phase angle; phi	Y, υ	upsilon
				Φ, ϕ	phi
				X, χ	chi
				Ψ, ψ	psi
				Ω, ω	omega

Corrosion Rate Conversion

Relationships among some of the units commonly used for corrosion rates

d is metal density in grams per cubic centimeter (g/cm³)

Unit	Factor for conversion to					
	mdd	g/m ² /d	μm/yr	mm/yr	mils/yr	in./yr
Milligrams per square decimeter per day (mdd)	1	0.1	36.5/ <i>d</i>	0.0365/ <i>d</i>	1.437/ <i>d</i>	0.00144/ <i>d</i>
Grams per square meter per day (g/m ² /d)	10	1	365/ <i>d</i>	0.365/ <i>d</i>	14.4/ <i>d</i>	0.0144/ <i>d</i>
Microns per year (μm/yr)	0.0274 <i>d</i>	0.00274 <i>d</i>	1	0.001	0.0394	0.0000394
Millimeters per year (mm/yr)	27.4 <i>d</i>	2.74 <i>d</i>	1000	1	39.4	0.0394
Mils per year (mils/yr)	0.696 <i>d</i>	0.0696 <i>d</i>	25.4	0.0254	1	0.001
Inches per year (in./yr)	696 <i>d</i>	69.6 <i>d</i>	25,400	25.4	1000	1

Metric Conversion Guide

This Section is intended as a guide for expressing weights and measures in the Système International d'Unités (SI). The purpose of SI units, developed and maintained by the General Conference of Weights and Measures, is to provide a basis for worldwide standardization of units and measure. For more information on metric conversions, the reader should consult the following references:

- *The International System of Units*, SP 330, 1991, National Institute of Standards and Technology. Order from Superintendent of Documents, U.S. Government Printing Office, Washington, DC 20402-9325
- *Metric Editorial Guide*, 5th ed. (revised), 1993, American National Metric Council, 4340 East West Highway, Suite 401, Bethesda, MD 20814-4411
- "Standard for Use of the International System of Units (SI): The Modern Metric System," IEEE/ASTM SI 10-1997, Institute of Electrical and Electronics Engineers, 345 East 47th Street, New York, NY 10017, USA
- *Guide for the Use of the International System of Units (SI)*, SP 811, 1995, National Institute of Standards and Technology, U.S. Government Printing Office, Washington, DC 20402

Base, supplementary, and derived SI units

Measure	Unit	Symbol	Measure	Unit	Symbol
Base units			Entropy	joule per kelvin	J/K
Amount of substance	mole	mol	Force	newton	N
Electric current	ampere	A	Frequency	hertz	Hz
Length	meter	m	Heat capacity	joule per kelvin	J/K
Luminous intensity	candela	cd	Heat flux density	watt per square meter	W/m ²
Mass	kilogram	kg	Illuminance	lux	lx
Thermodynamic temperature	kelvin	K	Inductance	henry	H
Time	second	s	Irradiance	watt per square meter	W/m ²
Supplementary units			Luminance	candela per square meter	cd/m ²
Plane angle	radian	rad	Luminous flux	lumen	lm
Solid angle	steradian	sr	Magnetic field strength	ampere per meter	A/m
Derived units			Magnetic flux	weber	Wb
Absorbed dose	gray	Gy	Magnetic flux density	tesla	T
Acceleration	meter per second squared	m/s ²	Molar energy	joule per mole	J/mol
Activity (of radionuclides)	becquerel	Bq	Molar entropy	joule per mole kelvin	J/mol · K
Angular acceleration	radian per second squared	rad/s ²	Molar heat capacity	joule per mole kelvin	J/mol · K
Angular velocity	radian per second	rad/s	Moment of force	Newton meter	N · m
Area	square meter	m ²	Permeability	henry per meter	H/m
Capacitance	farad	F	Permittivity	farad per meter	F/m
Concentration (of amount of substance)	mole per cubic meter	mol/m ³	Power, radiant flux	watt	W
Current density	ampere per square meter	A/m ²	Pressure, stress	pascal	Pa
Density, mass	kilogram per cubic meter	kg/m ³	Quantity of electricity, electric charge	coulomb	C
Dose equivalent, dose equivalent index	sievert	Sv	Radiance	watt per square meter steradian	W/m ² · sr
Electric charge density	coulomb per cubic meter	C/m ³	Radiant intensity	watt per steradian	W/sr
Electric conductance	siemens	S	Specific heat capacity	joule per kilogram kelvin	J/kg · K
Electric field strength	volt per meter	V/m	Specific energy	joule per kilogram	J/kg
Electric flux density	coulomb per square meter	C/m ²	Specific entropy	joule per kilogram kelvin	J/kg · K
Electric potential, potential difference, electromotive force	volt	V	Specific volume	cubic meter per kilogram	m ³ /kg
Electric resistance	ohm	Ω	Surface tension	newton per meter	N/m
Energy, work, quantity of heat	joule	J	Thermal conductivity	watt per meter kelvin	W/m · K
Energy density	joule per cubic meter	J/m ³	Velocity	meter per second	m/s
			Viscosity, dynamic	pascal second	Pa · s
			Viscosity, kinematic	square meter per second	m ² /s
			Volume	cubic meter	m ³
			Wave number	1 per meter	1/m

(a) kg × 10³ = 1 metric ton (tonne), or 1 megagram (Mg). (b) Preferred expression is 10^{−6}/K or 10^{−6}/°F as length units are unnecessary.

SI prefixes—names and symbols

Exponential expression	Multiplication factor	Prefix	Symbol
10^{24}	1 000 000 000 000 000 000 000 000	yotta	Y

(a) Nonpreferred. Prefixes should be selected in steps of 10^3 so that the resultant number before the prefix is between 0.1 and 1000. These prefixes should not be used for units of linear measurement, but may be used for higher order units. For example, the linear measurement, decimeter, is nonpreferred, but square decimeter is acceptable.

Policy on Units of Measure

By a resolution of its Board of Trustees, ASM International has adopted the practice of publishing data in both metric and customary U.S. units of measure. In preparing this Handbook, the editors have attempted to present data in metric units based primarily on *Système International d'Unités* (SI), with secondary mention of the corresponding values in customary U.S. units. The decision to use SI as the primary system of units was based on the aforementioned resolution of the Board of Trustees and the widespread use of metric units throughout the world.

For the most part, numerical engineering data in the text and in tables are presented in SI-based units with the customary U.S. equivalents in parentheses (text) or adjoining columns (tables). For example, pressure, stress, and strength are shown both in SI units, which are pascals (Pa) with a suitable prefix, and in customary U.S. units, which are pounds per square inch (psi). To save space, large values of psi have been converted to kips per square inch (ksi), where 1 ksi = 1000 psi. The metric tonne ($\text{kg} \times 10^3$) has sometimes been shown in megagrams (Mg). Some strictly scientific data are presented in SI units only.

To clarify some illustrations, only one set of units is presented on artwork. References in the accompanying text to data in the illustrations are presented in both SI-based and customary U.S. units. On graphs and charts, grids corresponding to SI-based units usually appear along the left and bottom edges. Where appropriate, corresponding customary U.S. units appear along the top and right edges.

Data pertaining to a specification published by a specification-writing group may be given in only the units used in that specification or in dual units, depending on the nature of the data. For example, the typical yield strength of steel sheet made to a specification written in customary U.S.

units would be presented in dual units, but the sheet thickness specified in that specification might be presented only in inches.

Data obtained according to standardized test methods for which the standard recommends a particular system of units are presented in the units of that system. Wherever feasible, equivalent units are also presented. Some statistical data may also be presented in only the original units used in the analysis.

Conversions and rounding have been done in accordance with IEEE/ASTM SI-10, with attention given to the number of significant digits in the original data. For example, an annealing temperature of 1570 °F contains three significant digits. In this case, the equivalent temperature would be given as 855 °C; the exact conversion to 854.44 °C would not be appropriate. For an invariant physical phenomenon that occurs at a precise temperature (such as the melting of pure silver), it would be appropriate to report the temperature as 961.93 °C or 1763.5 °F. In some instances (especially in tables and data compilations), temperature values in °C and °F are alternatives rather than conversions.

The policy of units of measure in this Handbook contains several exceptions to strict conformance to IEEE/ASTM SI-10; in each instance, the exception has been made in an effort to improve the clarity of the Handbook. The most notable exception is the use of g/cm^3 rather than kg/m^3 as the unit of measure for density (mass per unit volume).

SI practice requires that only one virgule (diagonal) appear in units formed by combination of several basic units. Therefore, all of the units preceding the virgule are in the numerator and all units following the virgule are in the denominator of the expression; no parentheses are required to prevent ambiguity.

in ammonia and ammonia compounds	733			
and carbonation	1061			
in caustic sodas	719			

<u>Index Terms</u>	<u>Links</u>				
Zinc and zinc-base alloys, general (<i>Cont.</i>)					
conservation strategies for	300				
corrosion products of	294	296			
corrosion products on	57				
corrosion rates of	43	45	67		
corrosion related to pH	291				
corrosivity categories for, based on					
corrosion rates	55				
in dental solders	911				
long-term atmospheric corrosion					
predictions for	54				
on marine vessels	267				
in reactor coolant	349				
sulfate-reducing bacteria (SRB) growth on	307				
used in outdoor environments	296				
Zinc anodes	75	93	94	266	936
on ship hulls	74				
Zinc chromate primer	212				
Zinc coatings	65				
Zinc coating weight, effect of, on service					
life of galvanized steel	1060				
Zinc embrittlement	999				
Zinc injection	405				
and hydrogen fugacity	405				
and hydrogen water chemistry (HWC)	356				
Zinc orthophosphate	10				
Zinc panels, corrosion products on	57				
Zinc phosphate	517				
Zinc-rich paints	999				
Zinc-rich primers	70	582			
Zinc sacrificial anodes	268				
for propellers and shafting	271				
Zirconium alloy corrosion	419				
Zirconium and zirconium-base					
alloys, general	406	415	723		
in acetic acid	678				
in ammonia and ammonia compounds	733				
in boiling water reactors	342

Zirconium and zirconium-base

alloys, general (*Cont.*)

in caustic potash	724	
in caustic sodas	719	
in chlorine water	708	
corrosion resistance of in hydrochloric acid (HCl)	684	
in dry chlorine	705	
ferric ion corrosion in during chemical cleaning	328	
in formic acid	676	
modulus, of titanium alloys		
hydrogen fluoride corrosion of	696	
irradiation effects on corrosion of	406	419
isocorrosion curve for	671	
isocorrosion diagram for and mercury	684	685
in moist chlorine	722	
nitric acid corrosion of	707	
orthopedics	671	
oxidation of	856	
in pharmaceutical industry	407	
in phosphoric acid	813	
pitting in	739	
polarization curves for	672	
in pressurized water reactors (PWR)	672	
recrystallized state (RX) of	362	
stress corrosion cracking (SCC) of	416	
sulfuric acid corrosion of	672	
tetragonal fraction in oxide in Zircaloy-4 vs. distance from the oxide/metal interface	664	
tetragonal phase transition	407	
zirconium-base amorphous-nanocrystalline alloys	407	
zirconium-niobium alloys	856	
	416	419
